Glossary

Acoustic tag A telemetry device that transmits data as a series of sounds (called pings) to a receiver.

Archival tag A telemetry device that records animal and environmental data on the device and then must be retrieved from the animal to get the data.

Chat tag An acoustic tag that stores the data and then sends it to an underwater receiver; it is only useful if the animal stays or returns to a site where the receiver is located.

Pop-up satellite tag A telemetry device that records animal and environmental data and then is released from the animal to pop up to the surface and send its data to a satellite, where it is then downloaded to scientists.

Satellite tags A telemetry device that sends data to Earth orbiting satellites.

Wildlife telemetry A special application of telemetry that records or sends data regarding an animal, that is, in its natural environment to allow remote monitoring and tracking of the animal.

Introduction

The pelagic ocean is one of the largest biospheres on the Earth, yet the patterns of species distribution, diversity, and abundance remain enigmatic. Intensive exploitation has led to dramatic changes in the structure of pelagic ecosystems due to the systematic removal of numerous species. The movements of top marine predators, such as tunas, billfishes and sharks, and hot spots (i.e., areas that attract large aggregations of one or more species), have been challenging to document due to the vast expanse of the oceanic environment and the difficulty of following animals in this undersea world. The physical and technological challenges of following large, fast, mobile marine predators such as tunas and sharks have been limited until recently. Consequently, the mechanisms linking physical forcing, zooplankton production, prey abundance and distribution, and top predator physiology, behavior, population structure and ecology remain elusive due to a lack of appropriate tools and approaches to investigate these processes. The influence of climate variability on the distribution of top predators is poorly documented and will require biological observations that span decades.

The tracking of marine fishes presents one of the most challenging problems in wildlife telemetry. Continuous tracking of water breathers submerged beneath the surface of the sea requires new techniques. Until recently, most knowledge of how large pelagic fishes use marine environs was derived from acoustic tracking tag technology. Pioneers in this research were Frank Carey at the Woods Hole Oceanographic Institute and AB Stasko at the Biological Station in St. Andrews, Canada as well as Fred Voegli of the University of New Brunswick, Canada. Acoustic tracking tags provide detailed information about vertical and horizontal movements. However, most tracks only provided a glimpse lasting several days of the routine behaviors or physiology of a fish because the scientist had to follow the animal to stay within range of the tag (i.e., up to 3 km) to detect and record the acoustic signal. The tracking of oceanic animals with an acoustic tag to learn behavior was labor intensive and required shipboard applications. More recently, the electronic tagging community, or biologging scientists, has applied increasingly sophisticated acoustic, satellite, and archival tracking techniques that have rapidly increased the data acquisition on horizontal and vertical movements, thermal physiology and oceanographic preferences.

In the past decade, there has been a rapid increase in the use of satellite-based tracking tags to study marine animals (**Figure 1**). The tags work most reliably on animals that breathe air (e.g., sea turtles, seals, and whales) since they regularly come to the surface. When the tag body is exposed, it can transmit to an Earth orbiting ARGOS satellite. The ARGOS system uses transmitters or position tracking terminals (PTTs) that send short radio signals at a frequency of about 401.650 mHz to polar orbiting satellites.

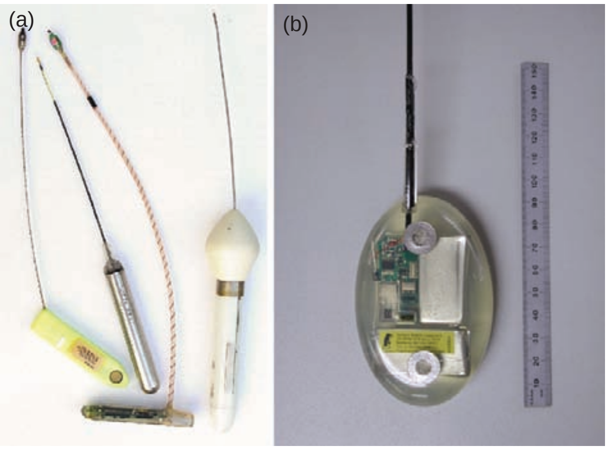

Figure 1 Electronic tags used for telemetry. (a) Left to right are archival tags that record data on light, temperature, and pressure and a pop-up satellite archival tag. (b) Single position only satellite tag.

The location of the transmitter on the animal is calculated using the Doppler shift in the frequency of transmissions received by the satellite as it makes a single pass over the tracking subject. By using this methodology, vertebrate animals have been tracked for thousands of kilometers. In the marine realm, the diving behavior of animals limits the use of the ARGOS system, especially when tracking water-breathing animals. By necessity, fishes and sharks are submerged in the water, making transmission of radio signals challenging. However, significant improvement in tag design and transmission capabilities specialized for fishes, including direct telemetry from towed tags or tags attached to shark dorsal fins as well as pop-up satellite archival tags, have made satellite tracking a powerful tool in the twenty-first century.

Despite these obvious challenges in the past two decades, the advancement of satellite tag technology for tracking fish has elucidated new information about the distributions, long-distance migrations, and population structure of marine fishes that typically have high dispersal rates (tunas, billfish, and sharks). Rapid advancement in satellite archival and direct uplinking tags has helped to unravel the migratory movements, diving behaviors and thermal preferences of a wide range of teleosts and elasmobranchs in an unprecedented decade of tagging advancements. In recent years, the capacity to keep satellite tags attached for longer periods (1–4 years) has led to the recording of philopatry behavior, and has helped to identify key foraging hot spots, as well as breeding and parturition areas. By archiving diving behaviors, the vertical habitat utilization of numerous marine pelagic species has been rapidly elucidated (**Figure 2**). These

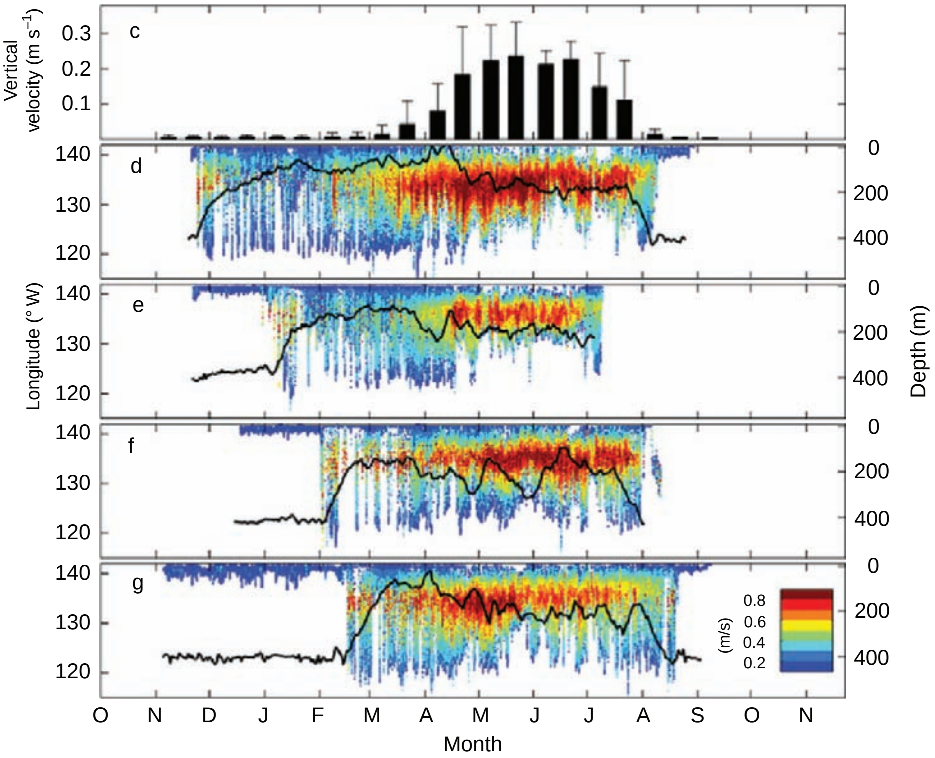

Figure 2 Extraordinary oscillatory diving by white sharks in the "White Shark Café," an offshore region half way between North American and Hawaii, revealed by using pop-up satellite archival tags attached to individuals. From Jorgensen SJ, Reeb CA, Chapple TK, *et al.* (2009) Site fidelity, homing and population structure in eastern pacific white sharks. *Proceedings of the Royal Society of London B*, doi:10:1098/rspb.2009.1155.

advancements, in combination with evolving genetic tools, are providing the opportunity for examining population structure in marine pelagic ecosystems which has rapidly advanced the prospects for conservation in the pelagic realm.

Recent developments in telemetry and biologging technologies also have greatly enhanced our ability to enlist apex marine predators to sample the marine environment, measuring ambient water temperature and chlorophyll concentration. These ‘animal oceanographers’ identify critical foraging habitat, migration corridors, and regions of high occupancy in global oceans. Enlisting animals is also relatively inexpensive compared to oceanographic research vessels and provides coverage in unique places such as under the ice at the poles (elephant seals) and in trans-oceanic corridors.

Acoustic Tags

Acoustic tags permit collecting data (most often individual identification codes, depth or temperature) from a single fish equipped with an ultrasonic tag that generates sound by driving an annular ceramic transducer at its resonant frequency. As electronic circuitry controlling tag function has been miniaturized, first with surface-mount and then with integrated circuit technology, tags have become small enough so that salmon fry can carry these tags. The constraints of transducer size and battery volume remain when large range or extended transmission life is required. Used in combination with real-time measurements of the physical and biological environment by the tracking vessel, acoustic tags have become powerful tools in examining environmental preferences of tuna. The tags encode the data as a series of ultrasonic pulses transmitted through the water column to a hydrophone and receiver on the ship. The use of multi-directional hydrophone arrays coupled with independent acoustic receivers and computers has improved estimation of direction and range of fish relative to the tracking vessel.

‘Listening stations’ are an exciting new acoustic technology. They are acoustic receivers that are moored at set locations and are able to communicate with, and log details of, tags that come within close range (250–500 m) over extended periods of time. Extensive tracking with listening stations is possible and is being used extensively with salmonids to study movements in riverine systems as well as enclosed embayments to examine migratory behavior and residency of fish. Acoustic listening stations installed at hot spots have also been used to track the movements of great white sharks (**Figure 3**).

The success of listening stations has spawned the development of ‘chat tags’, which combine many of the features of data storage, or archival tags (see below), with

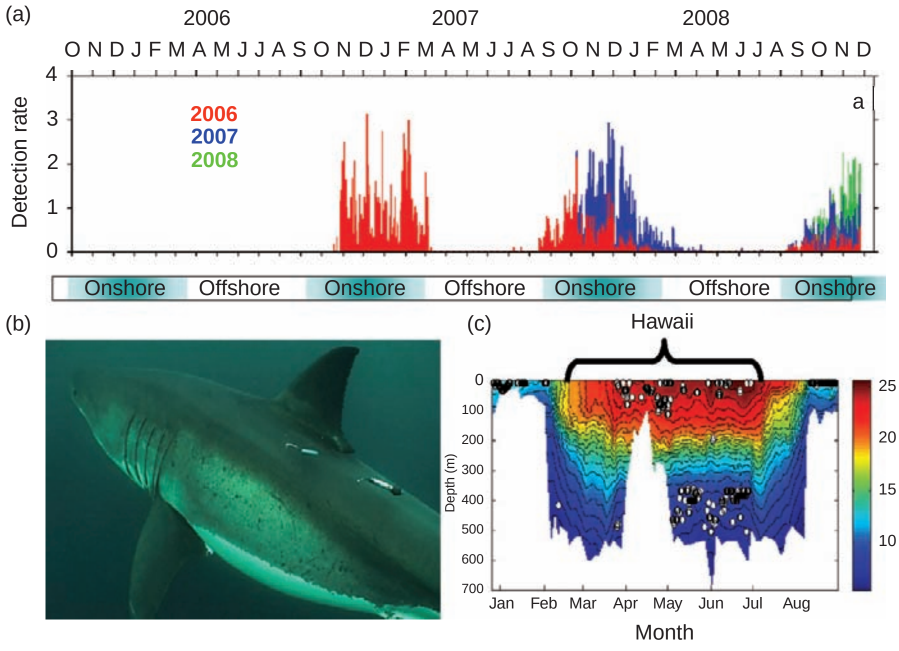

Figure 3 (a) Acoustic tags attached externally to white sharks provide presence and absence data in the vicinity of receivers placed in central California. Tags provide information on occurrence and residency. (b) A large white shark carrying two types of telemetry, an acoustic tag (forward) and pop-up satellite archival tag. (c) Pop-up satellite archival tags store data on depth and temperature that can be used to reconstruct the behavior of the shark during the period it carried the tag. In this example, the shark swam from California coastal waters to the waters off Hawaii. From Jorgensen SJ, Reeb CA, Chapple TK, *et al.* (2009) Site fidelity, homing and population structure in eastern pacific white sharks. *Proceedings of the Royal Society of London B*, doi:10:1098/rspb.2009.1155.

acoustic transmission of data when a fish comes close enough to a receiver. The receiver used with chat tags regularly send signals out to search for and identify tags within its range. Having received a positive response from a fish/tag, it then sends a command enabling the tag to download data via an acoustic signal. Chat tags have great potential in areas where fish are likely to return regularly to topographical or aggregating features. Mobile predators carrying receivers and chat tags yield the promise of a wired ocean community where predators and prey listen and detect one another. Importantly, listening stations and chat tags can record signals from multiple species allowing broad collaborations among scientists to cover the costs of the receivers.

Early Satellite Transmitters

Dr. Monty Priede made the first successful tracking of a gill-breathing animal using the ARGOS satellite system on a basking shark (*Cetorhinus maximus*) in 1984. The shark was tracked using a tethered tag over a period of 17 days. The basking shark was equipped with a ultrahigh frequency (UHF) radio transmitter and followed off the west coast of Scotland. The animal surfaced frequently and displayed rather localized movements. Simultaneous imagery from NOAA 7 AVHRR allowed for integration of the movements with sea-surface temperature data. The shark was following a frontal area.

Towed satellite tags were deployed in 1998 and 1999 to monitor the paths and habitat utilization of whale sharks *Rhincodon typus*, off South Africa (Indian Ocean) and in the waters off Honduras (Caribbean Sea). A Telonics satellite transmitter was packaged in a cylindrical flotation unit, and the tether employed a 1.5–7 m piece of airplane wire. Five whale sharks were tagged in this fashion by Scott Eckert, and diving profiles as well as horizontal movements were obtained. Animals were tagged by divers using tag anchors placed in the skin or musculature of the shark. Tethered tags provide real-time data about the habitat use and diving profiles of whale sharks, and may be recovered if they detach prematurely from the host animals. The whale sharks dove regularly to depths of >320 m, which may have contributed to premature detachment of the tags due to drag, and in later units the hydrodynamics of the tag were refined. Sharks tagged off the coast of KwaZulu-Natal, South Africa, traveled northwards. One shark tagged off the coast of Utila Bay Islands, Honduras, traveled to the Swan Islands, then moved along the Yucatan Peninsula and into the Mexico Basin, whereas the second shark tagged off Utila traveled to the coast of Belize. This study confirmed that tethered satellite tags are effective tools in monitoring travel paths and habitat use of whale sharks when real-time data are needed.

Towed tags were also placed on blue marlin (*Makaira nigricans*) by Drs. Heidi Dewar and Barbara A. Block in 1994. This package consisted of a Telonics transmitter that was placed in a streamlined tow body and was attached to the marlin with a 3–4 m tether made of airplane wire. This attachment and tag succeeded, providing several hits of low quality from marlin that traveled offshore from the point of tagging and release off Kona, Hawaii. However, overall few hits were obtained, and thus there was little ability to track the animals. After eight deployments using this tag configuration, no further attempts were made with this technology, and the scientists made a commitment to develop a detachable satellite tag.

PAT Pop-Up Satellite Archival Transmitting Tags

Pop-up satellite (tags often abbreviated with PSAT or PAT) were first placed on Atlantic bluefin tuna (*Thunnus thynnus*) in January of 1997. This novel tag technology allowed for a mobile predator to be tracked beneath the sea with the tag storing data on light, temperature, and pressure. The tag's shape and flotation were initially designed so the tag would be towed off the tapered portion of the bluefin's ventral region. At a preprogrammed time, an electrical impulse burned the wire that attached the dart to the tag, and the tag released from the fish to transmit its data. Original tags provided an endpoint and temperature data. As the tag evolved, a more sophisticated algorithm was developed that enabled position estimations that were based on light level-derived geolocation and sea-surface temperature-enhanced measurements. Because of the limitation of data transmission by satellite due to battery requirements, the logged data are compressed prior to transmission. The temperature and depth data are synthesized in the form of histograms and temperature depth profiles.

The PSAT or PAT tag has been extremely successful with thousands of deployments on tunas, sharks, turtles, and even marine mammals. The tags are unraveling many of the journeys of once secretive animals as they course thousands of kilometers under the sea. They are limited currently to about a year maximum deployment, primarily due to the challenges of keeping the tags on the animal.

Satellite Tags on Fishes and Sharks

The first directly attached fin tag was developed by Dr. Francis G. Carey, who designed a fixed position, dorsal fin-mounted, satellite tag that was placed on blue sharks (*Prionace glauca*) in 1993 in collaboration with the Sea Mammal Research Unit of the UK. The experiment was highly successful with high-quality locations obtained from sharks surfacing regularly enough to track the sharks along the Gulf Stream. The tag was robust and straddled the dorsal fin. The tags measured pressure (and thus calculated depth), speed, and position on a half dozen sharks in the North Atlantic. The longest track was over 2 months.

Direct telemetry off the dorsal fin of sharks provides an opportunity to enhance the capability of near real time tracking, data collection, and ocean observation. Most recently, this technique was applied to five species of sharks in the Tagging of Pacific Pelagics program (TOPP). Salmon sharks (*Lamna ditropis*) are large in body size and surface regularly due to behavioral thermoregulation in cold subpolar seas, making it easy to attach satellite tags. Tracks of over 3 years are routine on this shark, and makos have been followed for over 2 years.

Salmon sharks are apex predators in Alaskan ecosystems, yet little is known about their movements or population dynamics in Alaskan waters. Tagging through TOPP has been critical for documenting the extensive oceanic migrations of salmon sharks and enabled the characterization of their habitat use on oceanic scales (**Figure 4**). Tagging has demonstrated that salmon sharks utilize the inshore and nearshore waters of Prince William Sound, Cook Inlet, the Alaskan Peninsula, and southeastern Alaska shelf habitat throughout the year.

The same techniques utilized for studying the salmon shark were rapidly integrated with multiple species within the TOPP program. To date, over 10 species of sharks have been tagged with the single position only transmitting or SPOT tags with extremely successful tracking in species such as shortfin mako sharks (*Isurus oxyrinchus*), blue sharks and juvenile white sharks (*Carcharodon carcharias*). have also been tracked with limited success (Galapagos sharks *Carcharhinus galapagensis*, silky sharks *C. falciformis* and oceanic whitetip sharks *C. longimanus*).

Most teleost fish do not have appendages that break the surface of the water and can serve as a fixed attachment point for a tag as is possible with a shark's first dorsal fin. However, recently Holdsworth and colleagues obtained high-resolution satellite locations from striped marlin (*Tetrapturus audax*) using Argos transmitters attached to the upper lobe of the caudal fin. Twenty-six striped marlin were tagged off New Zealand (2005–07) and tracked as far as the central Pacific Ocean. Remarkably, the caudal fin mounted Argos tags generated

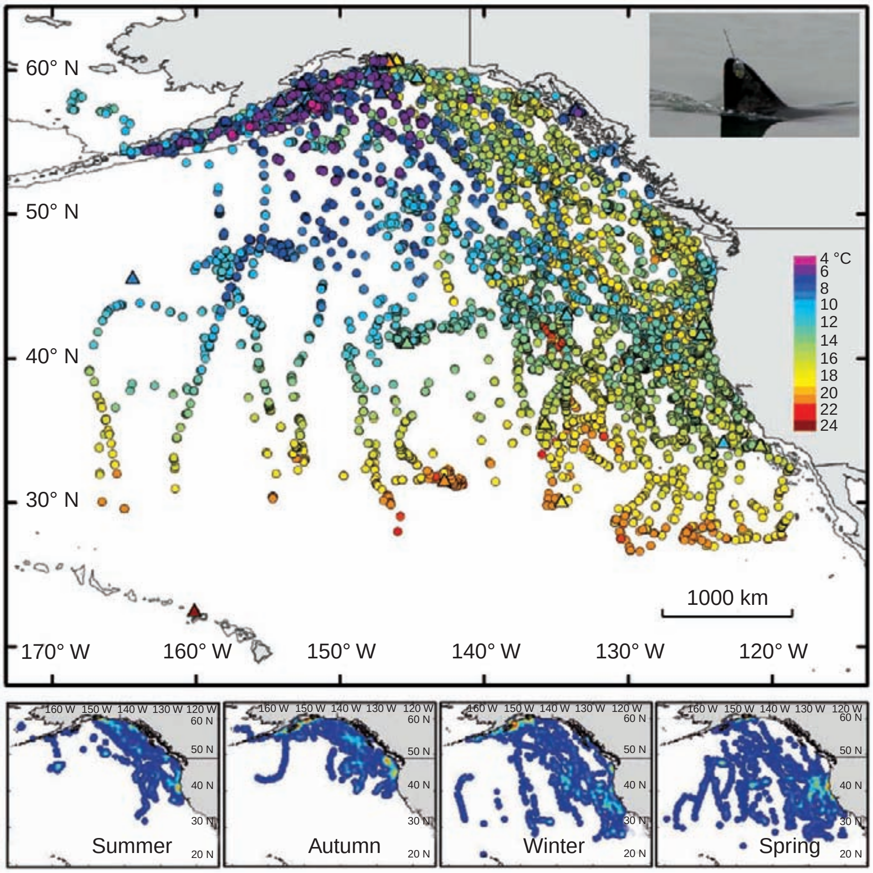

Figure 4 Single Position Only tags (SPOT) provide positions of salmon sharks, *Lamna ditropis*, carrying the tags. Sharks were tagged in Alaskan waters while foraging. Sea-surface temperature data experienced by the sharks are shown in color. From Weng KC, Castilho PC, Morrissette J, *et al.* (2005) Satellite tagging and cardiac physiology reveal niche expansion in salmon sharks *Science* 310: 104–106.

a significant number of high accurate positions of ±1 km or better. The caudal fin attachment methodology and antenna configuration were adjusted each season to improve transmission life and data quality, with the best results obtained in the last year of deployments (2007). The longest track duration was 102 days, with a total displacement of 4959 km and a total track distance from all locations received of 6850 km. Tag shedding and antenna failure appear to have limited the duration of SPOT tracks on fish. The high temporal and spatial resolution data revealed behaviors not previously observed in striped marlin, including associations to sub-surface bathymetric features. High-resolution location data will be valuable for generating robust behavioral state-space and habitat selection models.

Archival Tags

Archival tags are miniature computers, incorporating microprocessors, memory, and a suite of environmental and physiological sensors. They are low power tags, allowing data to be collected over many years (**Figure 5**). Specifications vary among manufacturers; however, the most advanced tags have light sensors capable of measuring variation in moonlight at depths of 100 m, 125 Mb or more of flash (nonvolatile) RAM memory, depth sensors providing accuracy of <1 m over a range of 1000 m, and thermistors capable of measuring temperature to within 0.1 °C over a range of 40 °C. They use 16-bit microprocessor technology and allow data to be collected from three to four sensors every few minutes for periods of up to 5 years (**Figure 6**). The nonvolatile memory allows data to be retrieved even after the tag's battery has run down.

Perhaps the most critical feature of an archival tag is the collection of data that can be used in estimating the position of the tagged animal. Researchers have used a variety of algorithms that combine the light measurements, water temperature, and depth data collected by archival tags to enhance the estimation of position. Estimating position from variation in light levels involves a suite of concepts and algorithms developed by Roger Hill augmented by sea-surface temperature enhancements by several authors including Steve Teo and B. A. Block (**Figure 7**). If fish remained on the surface and did not migrate long distances in short periods, estimating their position from archival tag data would be relatively straightforward. Unfortunately, most fish tend to make very rapid dives, often at sunrise and sunset – the times most critical for estimating latitude – and all are capable of rapid movement over large geographic scales. Thus, when using archival tags to estimate the position of tunas, we can expect systematic and random errors resulting from: equinoxes, light attenuation, water clarity, weather patterns, precision of astronomical algorithms, clock errors, resolution of light sensor, and behavior of the animal. Ingenuity has allowed scientist to overcome these difficulties, and using archival tags Atlantic bluefin have been tracked for as long as 5 years and 3-year tracks now exist in the Pacific Ocean (**Figure 8**). The capacity to record internal body temperature (tags are surgically placed in the peritoneal cavity), in addition to position and environmental variables, allows records of foraging, behavior, and environmental preferences. The duration of track and suite of data that can be obtained positions this type of tag as one of the most powerful in unraveling the mysteries of fish biology.

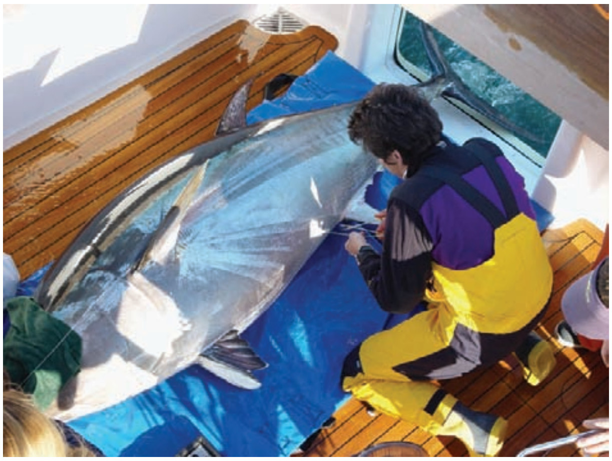

Figure 5 The author implanting an archival tag surgically in a giant bluefin, *Thunnus thynnus* off Nantucket, Massachusetts.

Multi-Species Tagging

The Census of Marine Life (COML) has enabled two large electronic tagging programs on the west coast of North America, Tagging of Pacific Pelagics (TOPP) and Pacific Ocean Shelf Tracking (POST). The two programs have shown the capacity to track multiple species simultaneously – putting tags into the peritoneal cavity or attaching them externally to track marine animals including salmon smolts, rockfishes, tunas, sharks, sturgeon, cetaceans, pinnipeds, sea turtles and squid over long distances and for multiple years, as they move along the North American continental shelf. TOPP and POST currently operate two of the largest undersea data acquisition networks, inclusive of ~4000 extant mobile tag platforms associated with predators that use the North American continental shelf and Pacific Ocean realms. TOPP has tested global positioning system (GPS) and conductivity, temperature, depth (CTD) tags, and has developed new algorithms for sampling the ocean environment (e.g., estimating *in situ* chlorophyll from tag measurements of light attenuation with depth). The programs have collected millions of ocean observations from COML animals, and maintain 300 permanent acoustic

receivers deployed in cross-shelf listening lines, island listening stations, or estuary and river basins.

TOPP identifies the spatial distribution of multiple species in an ecological context. To date, TOPP researchers have mapped common migration corridors for sharks, albatross, and tunas across the Pacific, and located multi-species hot spots for species utilizing the eastern Pacific. TOPP data have quickly revealed the seasonal and interannual variations in the patterns of movements of pelagic species throughout the North Pacific. Understanding the environmental cues underlying these patterns of habitat utilization is requisite for predicting patterns of predator distributions, diversity, and population structure.

The integration of the biological and oceanographic data sets generated from the electronic tagged animals elucidates how marine predators use physical features in oceanic ecosystems (i.e., mesoscale eddies and convergence zones). Tag data also allow TOPP scientists to observe behavioral responses of apex predators to climate-driven processes and have helped identify transitory hot spots in a dynamic ocean environment.

Animals as Ocean Sensors

Animals profile the water column as they move and provide *in situ* data much as man-made probes such as CTDs are capable of doing. Electronic tagging has the capacity to deliver ocean observations from undersea networks of animals in the open sea. The integration of tag-collected animal tracking data with environmental data from satellites and *in situ* oceanography has enabled scientists to study marine predator

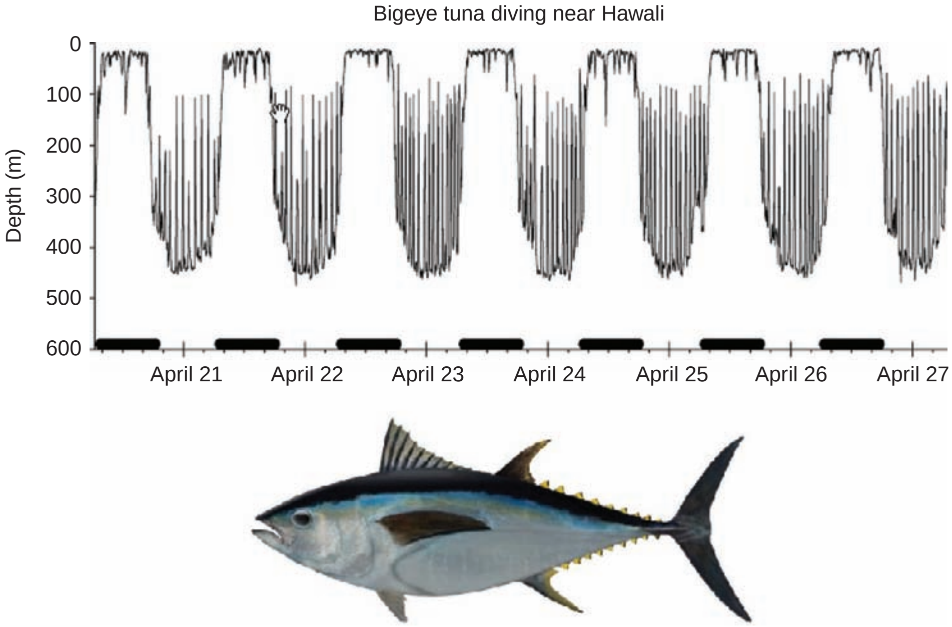

Figure 8 The diel behavior of a bigeye tuna revealed with an implantable archival tag in the waters off Hawaii.

habitat utilization, chart biological hot spots and movement corridors, and identify key areas and processes that concentrate coastal and pelagic fishes, sea turtles, marine mammals, and seabirds (**Figure 9**). These data on abundance and distribution of animals in a variable ocean environment are essential for designing ecosystem-based management plans in coastal and shelf habitats.

Glossary

Catadromous A fish born in the sea that moves into freshwater to grow and mature, before returning to the marine environment to spawn.

Conspecifics Other individuals of the same species.

Leptocephalus The leaf-like larva of an eel.

Neuromasts The sensory cells of the lateral line system in fish responsible for detecting movement.

Osmoregulation The physiological process of regulating the water content of bodily fluids and tissues.

Otoliths Small naturally formed stones found in the inner ear of most teleost fish.

Semelparous An organism that reproduces only once and then dies.

Introduction

The migration of European eels (*Anguilla anguilla*) to and from their spawning grounds in the subtropical, west Atlantic Ocean is one of the most remarkable feats of animal migration and also one of the most mysterious. Ever since the great Greek philosopher and scientist Aristotle first mused that eels “arose from the bowels of the earth” in the fourth century BC, generation after generation of biologists and oceanographers have become fascinated by the unique and, in many ways, exceptional life history of eels.

European eels, like all other anguillid eels, have a catadromous life, that is, they are born in marine waters, migrate to freshwater to grow and mature, before they return to the marine environment and migrate (typically 5000–7000 km, up to 9800 km from the furthest point in the eastern Mediterranean, **Figure 1**), spawn, and start a new generation. Like Pacific salmon and some other fish species, European eels are semelparous, that is, they only spawn once and then die.

To successfully complete their life cycle, eels undergo a number of transformations as they grow from egg to reproductively mature adult, and each stage involves its own adaptations that maximize the chances of successfully migrating to a new environment or location and reaching the next stage (**Figure 2**). In the following sections, we describe the main features of the migration of each of the stage of the European eel.

Larval Migration: The Early Years

Although the capture of eel larvae (called leptocephali, meaning leaf like, **Figure 3**) in the Mediterranean in the mid-nineteenth century led to the early belief that eels spawn there, the location of European eel spawning grounds is now known to be the Sargasso Sea, an area of over 1 million square kilometers located between 20–30° N and 48–79° W (**Figure 1**). This fact was established in the 1920s, when the Danish oceanographer Johannes Schmidt published his classic accounts of his surveys for the larvae of eels. He showed that the larvae of eels occurred at increasing size as the distance from the Sargasso Sea increased. In addition, the very smallest larvae, those that could be considered to be newly hatched from eggs, were only found in an area centered at 26° N, 60° W (**Figure 1**), predominantly during the months of April and May. The center of this bull’s-eye showed where the spawning grounds of the European eel must be. Schmidt also discovered that the earliest larvae of the American eel (*Anguilla rostrata*), as well as the European eel, were found in the same area in the Sargasso Sea, albeit slightly earlier in the year. More recent surveys have shown that American eel larvae are concentrated slightly further to the west than European eels. The location of the spawning sites poses the question of how European and American eel leptocephali migrate to their continental habitats up to 9000 km away (in the extreme case of European eels in the Mediterranean;

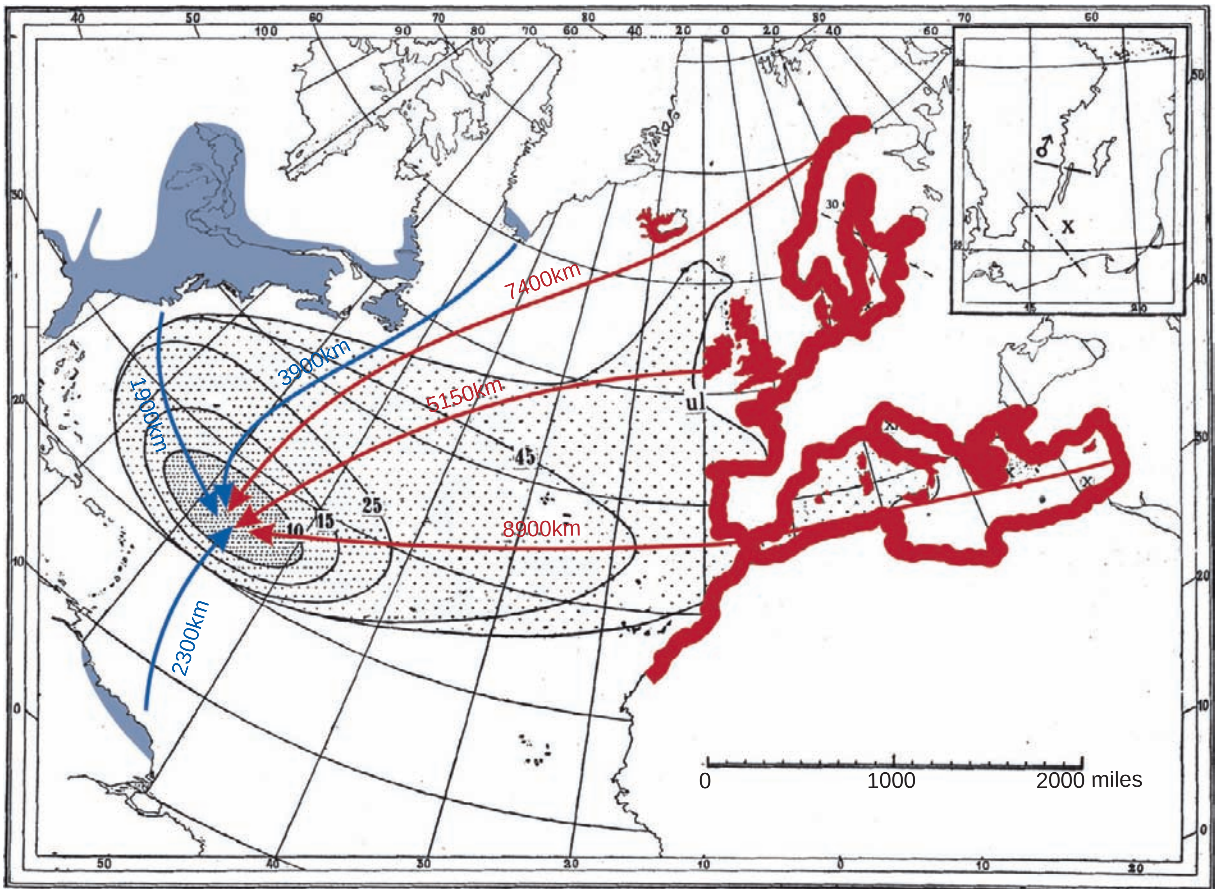

Figure 1 European eel. Spawning places (bounded by the innermost – 10 mm – curve); larval distribution (dotted area) and adult distribution (black strip) along the coasts of Europe and north Africa. The curves show the limits of occurrence; i.e., larvae less the 15 mm have only been found inside the '15' curve, larvae less the 25 mm have only been found inside the '25' curve, etc. The outermost curve (ul) denotes the limit of unmetamorphosed larvae. For the Baltic, '♂' and '30 cm' denote the limit of male eels and of eels less than 30 cm, respectively. 'X' denotes eastern-most limit of unpigmented elvers (Baltic and Mediterranean). The red arrows (added by the present authors) indicate the approximate migration distances for silver eels from northern Norway, western Ireland, and the eastern Mediterranean. Modified from Fig. 1 in Schmidt J (1923) Breeding places and migrations of the eel. *Nature* 111: 51–54.

Figure 1), as well as the transport mechanism that sends American eels west, and European eels to the east.

While there are still many details left to resolve, analysis of the ocean currents of the north Atlantic has shown that the leptocephali are transported principally by the Gulf Stream and North Atlantic Drift (**Figure 4**) to the European continental shelf over a period of between 1 and 3 years. The leaf-like shape of the leptocephali is thought to increase the effectiveness of this drift, but they are not just passive travelers on the ocean currents. Based on the fact that leptocephali spend much of their time in depths between 50 and 300 m, and therefore significantly deeper than the wind-driven surface currents, it is likely that orientation and directed swimming are also important factors in getting the larval eels to their destination. In fact, behavior is a significant factor that accounts for the separation of the paths of European and American eels; the American eels, which grow faster than their European cousins, are able to supplement the drift they receive from the Gulf Stream and arrive at the continental shelf on the eastern seaboard of the USA within 1 year of hatching. By contrast, the journey of the European eel larvae is much less clear, and is the subject of considerable debate. Based on modeling studies, as well as examination of the structure of otoliths (**Figure 5**), the leptocephali are thought to arrive at European coasts between 6 months and 3 years after hatching. This would put their travel speed somewhere between 10 and 50 km day^{-1}, based on a larval migration distance of 8500 km. How much of the migration distance is achieved via passive drift and active swimming is unknown. A 5-cm leptocephalus swimming at 2–3 body lengths per second would cover 8–13 km day^{-1}, and thereby considerably reduce the larval journey time by drift alone.

More recently, the location of the spawning area of the Japanese eel (*Anguilla japonica*) has been identified in the north-west Pacific Ocean in an area between the Philippines and the Mariana Islands. This discovery suggests a similar role for the North Equatorial and

Figure 2 The stages in the lifecycle of the European eel.

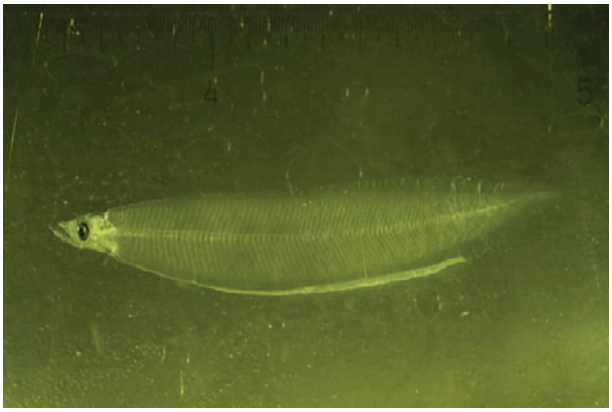

Figure 3 An eel larva (leptocephalus).

Kuroshio Currents (**Figure 4**) as a means of transporting leptocephali of this species to the coastal waters of eastern Asia, where the adults originate. Thus, the role of ocean currents in the movements and dispersal of the larvae of many eel species would appear to be a fundamental component of their life histories.

Migration from the Coastal Shelf: Life as a Glass Eel

It is estimated that much less than 1% of eel larvae successfully reach the European coast, and the arrival of leptocephali at the edge of the European continental shelf (typically defined as the 1000 m contour at the western edge of Europe) between September and February marks the end of this first and clearly perilous phase of life and the start of the next. Here, the leptocephali undertake their first metamorphosis into glass eels, so called because they are almost completely transparent.

Glass eels gather together in large shoals and migrate into shallower water and toward the coast. It is here that humans first detect them, usually in November, first at the southern edge of their distribution in Portugal (~40° N), which is the closest point to the spawning grounds.

Leptocephali have to travel a lot further to reach the more distant shelf edge further North, so monitoring stations start to report the arrival of glass eels at different times in France (January–March), and southern England and Ireland (February–April). Leptocephali that pass through the Straits of Gibraltar and into the Mediterranean, or that travel to the north of the UK toward Norway (April–May), are the last to reach shallow water, so they can only metamorphose and begin their inshore migration in June. As a result, the age of a cohort of glass eels varies a lot across Europe, being youngest in the south, and oldest to the north and east. Investigations into the age of glass eels using otoliths are still inconclusive, and put glass eels at between 6 months and 3 years old at first arrival.

The metamorphosis from leptocephalus to glass eel results in the development of a number of physiological and behavioral traits that enable the glass eels to find suitable growth habitat. Importantly, glass eels are able to identify the direction of the coast through a sensitivity to salinity and differences in odor between fresh and marine

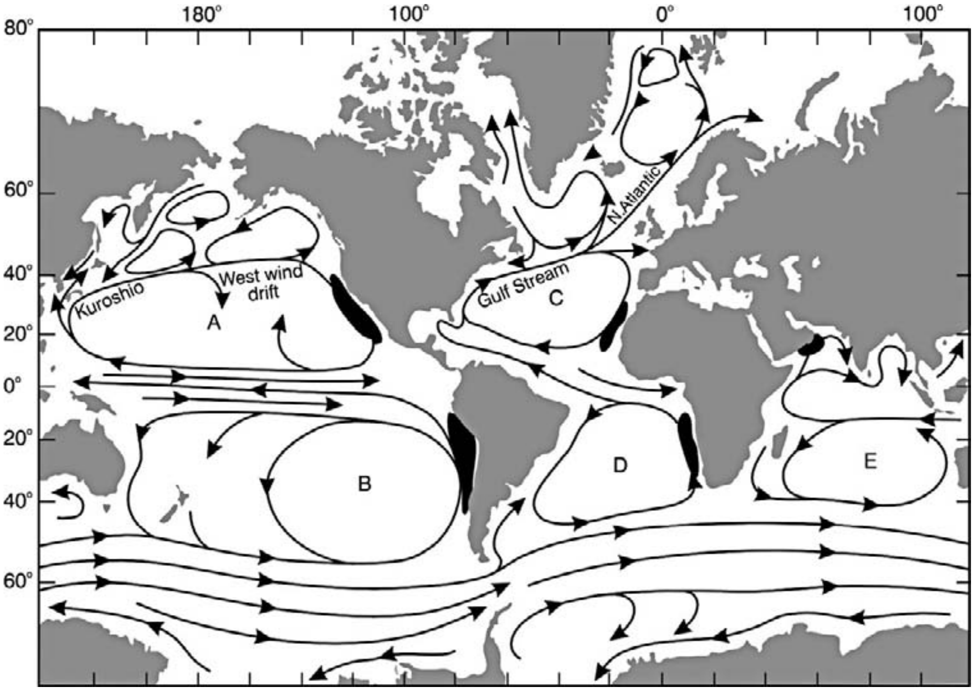

Figure 4 A simplified chart of the surface ocean currents of the world oceans. Main subtropical gyrals: A, North Pacific; B, South Pacific; C. North Atlantic; D, South Atlantic; E, South Indian. Important areas of upwelling in the eastern boundary currents (California, Peru, the Canary, and Benguela) and off Arabia are indicated in black.

waters. This ability is coupled with other behaviors that allow them to reach the coasts quickly and with minimal risk of predation. First, glass eels move from open water to the seabed, reducing the risk of predation. This also provides them with the opportunity to refuge from currents that would take them back out to sea. Glass eels also reduce their activity during the day, when predation risk is at its greatest. As they journey toward freshwater, glass eels need to be capable of tolerating water of gradually diminishing salt content. In adult eels, this is achieved in the gills (**see also Osmotic, Ionic and Nitrogenous-Waste Balance**: Mechanisms of Gill Salt Secretion in Marine Teleosts), which appear to be capable switching between excreting excess salts in seawater and extracting them in freshwater. It is not known, however, whether the same mechanisms operate in glass eels. Nonetheless, it is evident that these behaviors and sensitivities provide them with the means to locate the mouths of estuaries and reduce the risk of being eaten, while at the same time preadapting them for life in freshwater. So it is that, by converging toward freshwater sources, glass eels gather together in the company of thousands upon thousands of their conspecifics, and enter the lower reaches of rivers and begin their transition to the freshwater environment. This feature of their behavior is exploited by glass eel fisheries in most European countries of the Atlantic Arc, which scoop up the eels by the million for the restaurant or aquaculture trade. In recent years, however, catches of glass eels have declined dramatically, leading many to the conclusion that the sustainability of eel stocks in Europe is threatened.

Recently, evidence has emerged that all eels are not necessarily catadromous. A significant proportion of glass eels do not enter freshwater, but instead remain in the marine environment for their entire lives. This discovery was made by analyzing otoliths, or ear stones, of adult silver eels caught at sea. These structures are present in all bony fish, and grow by the incremental deposition of layers of aragonite (a crystalline form of calcium carbonate), which also traps trace elements present in the water in which the fish live. Studies in Japan showed that the otoliths of some eels did not contain the chemical signature typical of freshwater at all, only that of seawater. This discovery has since been repeated for other eel species, including the European eel, and demonstrates that the lifecycle and biology of eels is even more flexible and complex than previously thought. However, at the present time, while we know of their existence, almost nothing else is known about the biology or the marine eels behavior.

Life in freshwater

By the end of the glass eel phase, a new generation (cohort) of eels will have redistributed from the Sargasso Sea to most of the river systems in Europe. In fact, European eels are found in all European rivers draining to the Mediterranean, the North and Baltic Seas, and those rivers that drain to the Atlantic as far south as the Canary Islands. Eels can also be found in some rivers in Northern Africa and Asia that drain to the Mediterranean. Where eels are not found naturally, such as northern Scandinavia, eastern Europe, and even land-locked countries such as Austria, glass eels have often been translocated or stocked to rivers and lakes to provide a fishery for adult eels.

Once glass eels have entered freshwater and migrate up-river into their new habitat, and at about 6–7 cm in length, they undergo another metamorphosis and become elvers. By now, they are feeding on whatever suitably sized prey they can find, such as small invertebrates and this results in the development of pigmentation and of thicker bands of muscle. The goal of the elvers is to reach a habitat suitable for the growing phase of their lives. Thus, elvers migrate further and further from the estuaries that they entered, through the further development of the behavioral traits that enabled them to find their growth habitat. Hence, elvers continue to swim against the flow of the river, but with the tide (if within the tidal reach), restricting their activity to the hours of darkness. In fact, the compulsion to migrate against the flow is very strong and there are many stories of eels crossing barriers to their progress, such as man-made vertical drops or across fields, that would seem to be insurmountable to less able or determined fish. That they can do so relies in part upon this compulsion, and also in the fact that eels are able to absorb oxygen through their skin, thereby enabling them to remain out of water for long periods. During this time, the gills collapse, but then recover their normal form when the eel re-enters water. This feature of their physiology also comes in useful in the latter stage of their lives, when the compulsion to migrate down-river to the sea is equally strong.

The elver phase lasts until the complete freshwater form is attained, usually called the yellow eel, (but sometimes the green or brown eel) at approximately 30 cm in length.

Yellow eels can be found in almost all freshwater habitats, and generally avoid strong currents, moving little. Tracking studies, using implanted acoustic or radio tags, have shown that eels in freshwater may range no more than a few tens or hundreds of meters per day, within a limited home range of, at most, a few kilometers. (Eels living in marine waters seem to have similar habits: local, rather than extensive, movements.) They retain this habit as they age, but tend to relocate their home range further up-river. In consequence, larger eels are usually found further from the sea, and at a lower density. They may remain in freshwater for many years: the oldest European eel ever captured in freshwater was estimated to be >90 years old and the largest ever captured was 147 cm and several kilograms in weight. In general, however, they complete their growth phase within 20 years or less, and at 35–65 cm for males and 50 to >130 cm for females. The factors that trigger the transition from the growth phase to the maturation and marine migration phases are not well known, because the range of size and age at which yellow eels enter the silver eel phase is so wide.

The Downstream Migration: Back to the Sea

Despite their potential longevity and large size, eels in freshwater should not really be considered to be adults in the biological sense because their sexual organs only develop fully once their spawning migration is underway. While this is an unusual strategy, the capacity to have a long growth phase (if necessary) provides the flexibility for eels to attain the size and condition required for them to return successfully to the Sargasso Sea and have a chance to spawn. With this flexibility, eel populations are probably more resilient to changes in the productivity in their growth habitat than would otherwise be the case.

However, just attaining the right size and body condition is not enough, because before they can migrate downstream and escape to the sea to spawn, eels must undertake their second major metamorphosis. This process is called silvering, so called because eels change color from yellow (or brown/green) to silver (actually, the belly becomes silvery-white while the sides and back become a dark bronze color). However, despite its name, silvering is not just a superficial change in color (**see also The Skin**: Coloration and Chromatophores in Fishes), but a fundamental suite of physiological and morphological changes that preadapts eels to the next stage of their life: the oceanic spawning migration.

The counter-shading coloration that eels adopt is typical of oceanic pelagic fish, and reduces the risk of detection by predators, but there are several other major adaptations.

Perhaps the most obvious external change is the enlargement of the eyes that, along with an increase in the number of rods on the retina (**see also Vision**: Extraretinal Photoreception), adapt eels to seeing even at very low light levels. Other morphological changes include the development of thicker skin (and more mucus to protect it), a darkening of the pectoral fins, and the appearance along the lateral line of neuromasts, which increase the sensitivity of the eel to movements in the water around them. These morphological changes, while distinct, are nothing compared to the dramatic changes to the physiology and structure that are taking place internally.

Most importantly, the fat content of eels increases considerably during the silvering process, and reaches between 25% and 30% of body mass, about 2–3 times that of farmed salmon. This energy store is fundamental for the long migration ahead. Sufficient fat stores are required because eels, once silver, do not feed and the gut, or alimentary canal, ceases to function in digestion. Without sufficient fat, eels may be unable to complete the migration at all or they may not be able to produce enough good quality eggs (or sperm) at the end of their journey to the spawning grounds. Without a digestive function, the gut decreases in length and its walls become thinner, and its only remaining function is to absorb water and help maintain the osmoregulatory balance (**see also Osmotic, Ionic and Nitrogenous-Waste Balance**: Mechanisms of Gill Salt Secretion in Marine Teleosts).

Secondly, the specialized organ that controls buoyancy, the swimbladder (**see also Buoyancy, Locomotion, and Movement in Fishes**: Buoyancy in Fishes), also becomes more vascularized, and its walls become thicker. These adaptations enable better gas secretion and retention, so that any required changes in buoyancy, while in the ocean, can be achieved quickly and efficiently.

Finally, eels must adjust their ionoregulatory and osmoergulatory processes for a life in seawater rather than freshwater. Teleost fish regulate the osmotic concentration of their body fluids at about 30–40% of the level of oceanic seawater (**see also Osmotic, Ionic and Nitrogenous-Waste Balance**: Mechanisms of Gill Salt Secretion in Marine Teleosts). Fish in freshwater, therefore, must deal with the osmotic entry of water and diffusional loss of salts via the gills and gut. To compensate, they produce large volumes of dilute urine. Marine fish have the opposite problem of osmotic loss of water and diffusional entry of salts. As a consequence marine fish drink seawater and excrete excess salts. While most fish species are adapted to live only in one environment or the other (stenohaline) and will die if transferred, a few species are euryhaline and able to move between seawater and freshwater. Some euryhaline species (e.g., salmon) have to make substantial physiological adaptations to survive such a change of environment and are only able to move between seawater and freshwater at specific points in their life cycle. However, eels (such as flounder) are able to move into seawater at any time, despite their longevity in freshwater habitats. This ability to move between seawater and freshwater relies on the capabilities of the organs that regulate water balance (the gills, gut, and kidney) and the tissues (principally the adrenal gland) that produce the hormones that control them.

Clearly, these changes are as considerable as they are necessary. In some ways, silvering can be likened to puberty because, at its heart, silvering transforms eels from their adolescent yellow eel form to full adulthood. Like puberty, silvering involves a series of complex hormonal changes that are only complete once the eel reaches full sexual maturity. However, it is not yet clear what factor or factors trigger silvering because the process is quite gradual and intermediate stages can be identified. Silver eels can be all sizes and ages, but generally tend to be smaller and younger to the south, and males are smaller and younger than females. Indeed, the exact definition of a silver eel is still, after many decades of study, somewhat elusive. However, there is now some evidence that somatic growth plays at least a part in the silvering process. Eels at the migratory stage show a higher growth rate than resident eels, regardless of their origin, and somatotropin (a natural animal hormone that stimulates growth and cell production) has been found to be highest in premigrant eels. There is also evidence that the cortisol (**see also Hormonal Control of Metabolism and Ionic Regulation**: Corticosteroids) is important in the initiation of migration. This hormone may play a part in the mobilization of energy stores in preparation for the long journey ahead and is also thought to be involved in increasing Na^+, K^+-ATPase activity (an important osmoregulatory enzyme found in the chloride cells of the gill epithelium).

Nonetheless, it is clear that for an eel to begin its spawning migration, it must at least be partially silvered and therefore preadapted to marine life. Once so, eels are then able to undertake the first stage of the spawning migration: escapement to the sea. Similarly to the silvering process, the cues that eels use to choose when to start their downstream migration appear to vary and are dependent upon a number of different factors. Whatever the cause, each autumn (August through December), hordes of eels start to migrate downstream and escape to the sea. In this process, it appears that decreasing (rather than absolute) temperature and shortening day length are key seasonal factors that trigger the onset of migration.

The escapement occurs at night, usually during the period of the new moon, when light is at a minimum, and typically during periods of high rainfall. Progress of eels downstream can be rapid, with eels moving many kilometers each night, but their migration may also be interrupted by natural obstacles, such as pools or dead-ends, or man-made blockages, such as weirs or hydropower stations. In consequence, and because there are only 3 or 4 days of each phase of the moon when eels will migrate, it may take eels up to 3 months (or perhaps more) to travel downstream to the sea. The further away from the Sargasso Sea that the eels reside, the earlier that the downstream migration occurs, a phenomenon assumed to ensure that the arrival of eels from different locations at the Sargasso Sea is synchronized. Thus, most eels leave Norwegian and Swedish rivers as early as August, whereas the peak season for eel escapement in Ireland and France is October through December. However, should the eel get the timing wrong, or the eel get trapped on the downstream migration, all is not lost. Until the eels escape to the sea, and become fully marine, the changes in morphology and physiology caused by silvering are reversible, and provide another chance at escapement in later years.

The Spawning Migration: Into the Big Blue

On leaving their freshwater homes, ahead is a 6-month journey of up to 9000 km or more, across an ocean that reaches over 5000 m in depth. Depending on the location and month of departure, this requires an average swimming speed of between 0.3 and 0.6 m s^{-1}. Although this may not sound too much of an effort, consider that silver eels vary in size from 35 cm (the smallest males) to 1.3 m (the largest females). Thus, the smallest males (0.3 m long) will be required to swim at least 1 body length per second, on average, for 6 months – no mean feat. The largest females will have to swim at up to 0.5 body length per second for 4 months. Even though the largest females do not need to move proportionately as fast as males, with a cross-sectional area far greater than the smallest males, they will have to expend more than 8 times as much energy to overcome the drag as they move through the water.

The journey ahead is long however, and the immediate challenge to eels when they leave their home rivers is to navigate through the relatively shallow waters (generally <200 m) of the coastal shelf to reach the open Atlantic Ocean. The difficulty of this task varies with the starting location. From countries that border the Atlantic, such as France, Ireland, or Norway, the journey is relatively simple. From countries bordering the Mediterranean or Baltic Seas, the journey is more arduous and requires the negotiation of one or more passages (e.g., the Gibraltar or Dover Straits), which are likely to slow the progress and increase the duration of the coastal phase of the spawning migration.

The coastal phase of the spawning migration was initially studied through the use of mark-recapture experiments using simple tags. The recapture, usually by fishermen, of tagged eels at a point distant from their original release, can reveal the direction and routes of migration and provide some ideas of the speed at which migration progresses. Generally, eels migrate in coastal waters in a fairly directed way. For example, eels tagged on the eastern Swedish coast in the Baltic Sea migrate west at a speed of ~20 km day^{-1} toward the junction between the Baltic Sea and the Kattegat (the gateway to the North Sea). Recent use of either acoustic tags that send a signal to a tracking vessel, or electronic tags that record data and are recovered through eel fisheries have increased the sophistication of such studies, adding speed and directional data that can reveal behaviors. What they show is that eels have a diel vertical migration: they move into deeper water, or to the seabed, in the day, and into shallow water at night. The purpose of these movements is unclear, but may relate to predator avoidance (by hiding on the seabed during the day) and/or navigation (searching for currents or migratory cues). It is unrelated to feeding activity, however, because silver eels lose their ability to digest food once they have metamorphosed.

Much less is known about the behavior of eels once they leave coastal waters and move into deeper, oceanic waters, for several reasons. First, the migration routes of European eels are unknown, and as a consequence all attempts to capture eels in the ocean have failed. This includes several concerted attempts to capture eels at their spawning grounds in the Sargasso Sea. Determining the migration routes (and depths) therefore requires either following eels from the time that they escape from rivers, or capturing silver eels in rivers and transporting them to the ocean before tagging and releasing them. However, because the practical difficulties of following eels for extended periods are so great, these types of studies have succeeded only in recording the migration for relatively short periods of time. In the first case, studies using acoustic tags have tracked eels for up to several days and over distances of a few hundred kilometers, while studies using electronic tags have succeeded for recording data for up to 71 days (in the Baltic Sea), but in neither of these cases did the eels enter open oceanic waters. In the second case, the pioneering translocation studies of Freidrich W Tesch in the late 1970s and early 1980s stand out. Tesch caught silver eels in the Baltic and then transported them aboard ship to various locations, including the Mediterranean and Sargasso Sea, before implanting acoustic tags and releasing them again. The data showed that eels could dive to depths >700 m and travel at speeds of up to 0.8 m s^{-1}. As for eels in coastal waters, diel vertical migrations were a notable feature of the behavior. Despite these valuable results, empirical evidence on the oceanic spawning migration of European eels remains elusive. More recently, the development of small satellite communicating electronic tags has revived hope that the spawning migration can be recorded. Successful application of the technology to the long-finned eel (*Anguilla dieffenbaachi* L.) has now been repeated for the European eel, and the preliminary results, while falling short of revealing the spawning grounds, suggest that it may not be too long before the full migration is described.

While empirical data on migratory behavior may currently be lacking, a considerable body of evidence has been collected on the capability of European eels to undertake lengthy migrations. Chief among these have been swim tunnel experiments that have revealed the endurance and efficiency of long-distance swimming. The experiments, undertaken at the University of Leiden in Belgium, showed that female eels have an optimal speed of approximately 0.6 m s^{-1} and that they are capable of continuous swimming at 0.5 m s^{-1} for at least 173 days (which would allow them to cover 5500 km). This achievement resulted in a surprisingly small weight loss – eels of ~900 g lost only 60 g of fat This in part can be attributed to the fact that eels have a mode of swimming that is between 2 and 4 times as efficient as that of other species of teleost fish such as salmon. Another remarkable feature of the results was that the eels used up muscle reserves of carbohydrate and protein at the same rate as fat. This not only ensures that the buoyancy of the eel tissue remains unchanged but also maximizes the reserves of fat left at the end of the migration for conversion into the next generation of eels.

Concluding Thoughts

The lifecycle of the European eel has fascinated scientists, fishermen, and natural historians for many centuries. While many aspects of their behavior and biology during their freshwater phase have been elucidated, our understanding of the marine migrations, both as larvae and subsequently maturing adults, continues largely to remain a mystery. However, concern over the substantial decline in eel recruitment of the past two decades has rekindled interest in eel biology and, with the help of new tagging technologies, science is now on the brink to solving one of the last great mysteries in natural history. We can only hope that, when combined with other knowledge of the impacts and threats eel face during the freshwater phase of their lives, this new understanding will allow us to formulate and implement conservation measures that will ensure their continued survival.

The migration is also a risky endeavor, and yet European eels have survived through ice ages and changes to ocean circulation patterns. However, current trends in eel stocks and eel recruitment point to a serious decline in numbers over the last 30 years or so. The new threats and cause of the decline have not been established and is likely to be the accumulated effects of a number of possible factors that include: overfishing, loss of habitat, climate change, barriers to migration (upstream or downstream), disease (viruses and parasites), and industrial pollution. Of these, the latter four are particularly pertinent to eel migration, each in a different way. Climate change, for example, is likely to affect eels at all stages of their lifecycle, by increasing development rates of eggs and larvae (potentially increasing starvation mortality) and by modifying the direction and speed of the oceanic currents that help to transport leptocephali. Similarly, industrial, man-made pollutants such as polychlorinated biphenyls (PCBs) are very resistant to degradation and accumulate easily in the body fat, which is very high in silver eels. PCBs through their endocrine effect and by reducing the resistance to infectious agents could easily compromise adult migration and the survival and development of eggs and larvae.

Glossary

Anadromy Life-history strategy entailing reproduction and early rearing in freshwater followed by a significant growth phase in seawater.

Natal homing The phenomenon whereby animals return to the site where they were born to reproduce themselves.

Osmoregulation The maintenance of consistent cellular or organismal fluid composition and volume.

Pacific salmon Fish of the genus *Oncorhynchus* in the family Salmonidae.

Semelparity A reproductive strategy whereby an individual reproduces only once within its lifetime.

Smoltification Series of physiological and morphological changes a fish may undergo when migrating from freshwater to seawater.

Introduction

Pacific salmon (*Oncorhynchus* spp.) are well known for their large-scale migrations that can take them thousands of of kilometers from inland freshwater systems, where they begin their lives, to rich and fertile ocean habitats for feeding. Ultimately, they return to their natal stream to reproduce, before this lifecycle is repeated by their offspring (see **Figure 1**).

The migratory strategy of reproducing in freshwater, yet feeding primarily in marine waters is known as anadromy. Of the ~35 000 species of fish, ~2.5% are known to undertake migrations, and of that small percentage only 16% participate in anadromous migrations. Unlike Atlantic salmon (*Salmo salar*), Pacific salmon are semelparous, meaning that they die after spawning (**Figure 2**). The dead adults provide energy and nutrients for stream ecosystems, which benefit their own offspring after they hatch and begin to feed independently. This means that a fish that fails to mature and reach spawning grounds and reproduce will have zero fitness, contributing no genetic information to future generations. Indeed, not all fish that hatch return to spawn. Typical success rates are less than 1% for alevins. Even during the upriver migration phase, significant mortality can occur (e.g., up to 90% mortality from river entry to spawning grounds for some stocks in some years).

As described in **Fish Migrations**: The Biology of Fish Migration, migration represents a complex interplay of behavior and physiology. This interplay is perhaps best exemplified by the Pacific salmon (genus *Oncorhynchus*) given the many natural challenges that these fish encounter during migration including predators, dynamic river flows and ocean currents, diseases, parasites, variable temperatures, and dramatically variable salinities. In addition, migrating salmon face additional anthropogenic challenges, such as fisheries exploitation, habitat alteration, and physical barriers (e.g., dams, climate change, and other ecosystem alterations).

There are three aspects of Pacific salmon migration that make them particularly remarkable. The first is their navigational ability, which enables them to migrate from the high seas to the exact steams where they themselves were spawned. Such natal spawning fidelity is rare among fish and among other animals. Even so, fidelity for home stream does vary among Pacific salmon species. Sockeye salmon (*O. nerka*), for example, tend to exhibit low rates of straying (<1%) whereas pink salmon (*O. gorbuscha*) tend to show less preference for natal sites.

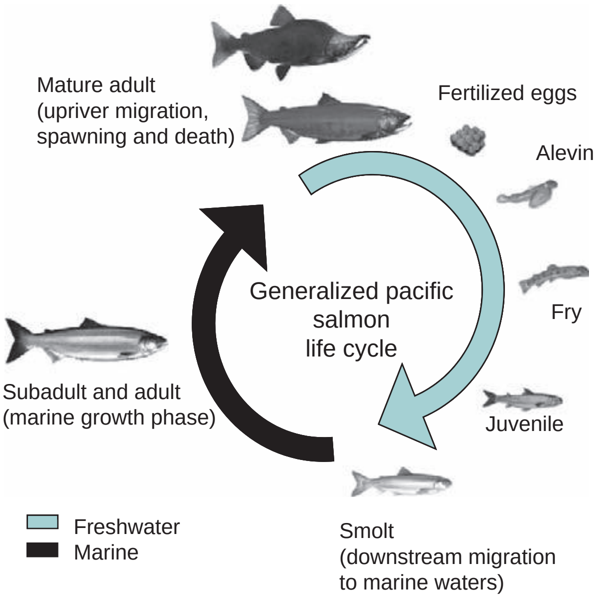

Figure 1 Generalized life cycle for Pacific salmonids.

Figure 2 Dead sockeye salmon on spawning grounds. After reproduction, most Pacific salmonids die, a characteristic of semelparity. The carcasses provide nutrients for the developing offspring as well a wide variety of plant and animal life (e.g., bears, bald eagles).

The second remarkable aspect is their ability to transition from freshwater to saltwater during their seaward migration in a process known as smoltification. When they return as adults, they reverse the process, transitioning from saltwater to freshwater. Many fish species would die when exposed to such a challenge, yet this is the norm for Pacific salmon, despite the need to remodel gill functions as well as their entire osmoregulatory apparatus (**see also Osmotic, Ionic and Nitrogenous-Waste Balance**: Osmoregulation in Fishes: An Introduction).

The third remarkable feature is the homeward river migrations of spawning adult salmon. Before they enter the river, they stop feeding and then complete a freshwater migration, sometimes in excess of 1000 km, using stored body energy, principally fat. Not only is this body fat used to fuel the entire spawning migration, but the energy must also be in sufficient quantities to support the maturation process: development of secondary sexual characteristics, the production of sperm and eggs (**see also The Reproductive Organs and Processes**: Vitellogenesis in Fishes and Regulation of Spermatogenesis), and the act of reproduction itself. Given these challenges, it is remarkable that any individual Pacific salmon is successful. Yet, every year, millions of Pacific salmon continue returning to natal spawning grounds throughout the north Pacific rim, extending from Japan and Russia in the western Pacific, northwards to Alaska, the Yukon, British Columbia, and south into Washington, Oregon, and California. Pacific salmon, however, are not found south of the equator except as an introduced or cultured species.

Although the most remarkable and notable migrations are the large-scale seaward and spawning migrations, Pacific salmon make their first migrations within hours of hatching! To fill their swimbladders for the first time, they must migrate from the gravel, where they are hatched to the water's surface to take this first gulp of air, otherwise they die. Other small-scale migrations include the day–night vertical migrations taken by juvenile salmon in rivers, lakes, and coastal seawater, usually for foraging and predator evasion. There are many other examples of specific small- and large-scale migrations made by Pacific salmon, but because there is immense variation within and among different species, we will generalize the various migratory phases of salmon and focus on what we will term the 'generic Pacific salmon'. By so doing, we will describe seven principal migratory phases that occur throughout the lifetime of a generic salmon.

Given that the vast amount of research that has focused on the downstream smoltification migration and the upriver spawning migration, we provide an in-depth description of these two particular phases. Just because the bulk of research efforts have been directed toward the larger-scale and relatively conspicuous migrations such as upriver migrations, this does not mean that the smaller, less conspicuous migrations are not important. All migratory phases of salmon are important for the survival of the species. Indeed, for an animal with only one life-time opportunity to reproduce, all migratory phases could perhaps be considered essential, irrespective of scale. Furthermore, sockeye, coho (*O. kisutch*), Chinook (*O. tschawytscha*) and pink salmon are the most well-studied salmon, particularly with respect to migration and physiology. However, other Pacific salmon including chum and masu salmon, as well as the Pacific salmonid steelhead (henceforth regarded as a Pacific salmon), make the same migrations during their lifetime and should not be overlooked. Although we have structured this article around the migratory life history of a generic Pacific salmon, we will provide examples and data from all species where available.

Larval Developmental Migration

The fertilized eggs of all Pacific salmon (including steelhead) hatch into young alevin in the gravel and rocky substrates where the mother laid them. These small salmon fuel early development using endogenous energy stored in their yolk sac. As swimming muscles develop and the yolk sac becomes nearly depleted, the alevin must forage. However, the first step is to obtain neutral buoyancy (**see also Buoyancy, Locomotion, and Movement in Fishes**: Buoyancy in Fishes) and to do so they must migrate from the safety of the gravel to the surface to fill their swimbladder. From the moment this first migration begins, the fish are exposed to a variety of threats including swift water currents and various predators.

Although the timing of this migration is critical, researchers know little about the specific environmental cues or physiological processes that mediate the initiation of this first migration. The endocrine system, and in particular the thyroid hormones, appear to be associated with photic sensitivity, which may serve as a proximate control for the timing of migration; alevins typically attempt the migration at night rather than day to minimize exposure to predators. Gas exchange occurs almost exclusively at the skin surface rather than at the gills during this phase of life (**see also Ventilation and Animal Respiration**: Respiratory Gas Exchange During Development: Respiratory Transitions), facilitated by dense capillary networks surrounding the yolks sac and a high surface area to body mass ration. The primary role of the gills at this phase, before they eventually are used for gas exchange, is for ionoregulation (**see also Osmotic, Ionic and Nitrogenous-Waste Balance**: Osmoregulation in Fishes: An Introduction).

Migration to Larval Feeding Grounds

River spawning is, by far, the most common strategy among salmonids. Alevins of many species of Pacific salmon then migrate to a nursery area (the river itself or a nursery lake) by either passive drifting or sometimes volitional swimming. During this period, they are termed fry. Sockeye salmon more typically migrate to a nursery lake, unless they were spawned in a lake.

The motivation for migration by sockeye fry to a lake-nursery environment is to take advantage of the growth potential offered by the productive lake environment, but getting there successfully from the natal stream requires important behavioral decisions to minimize energy use and avoid predators while migrating. Several physiological and behavioral adaptations facilitate this process, which vary depending upon whether the young fry move downstream or upstream to reach the nursery lake (i.e., moving with or against the water flow). The locomotory capabilities, muscle development, and anaerobic capacities of salmon fry can differ based on whether they migrate upstream to larval feeding grounds or downstream; upstream migrants have better swimming performance, muscle development, and anaerobic capacity. With regard to navigation to the lake environment, it is likely that rheotaxis (i.e., orientation against the water current) is the dominant orienting mechanism by which fry find their way upstream to a nursery lake, although olfaction may also play a role in fry, which must cross a tributary on the way to the nursery lake, or when fish must first swim down one river and then up another to reach the lake. These migrations generally occur at night, presumably to further minimize predation risk. Furthermore, life in nursery lakes involves diel vertical migrations associated with prey searching.

Smolting and Migration to Sea

The transition by salmon from freshwater to seawater is undoubtedly the best studied of all fish migrations. The principal motivation for seaward migration is the massive feeding and growth potential afforded by the nutrient-rich, open ocean compared with the nutrient-limited freshwater systems where salmon spawn. The smoltification (i.e., the transition physiologically into seagoing forms) process is an inherently stressful and risky period in the life cycles of salmon, and this phase is often considered a survival bottleneck, in which mortality is high. To survive this period, the smolts must carefully time this event to arrive at the ocean at an optimal time when ocean currents are favorable for their movement into coastal areas and when food resources are available. They must also overcome the challenges associated with the transition between hypoosmotic freshwater and hyper-osmotic marine environments, which imposes significant physiological stress (**see also Osmotic, Ionic and Nitrogenous-Waste Balance**: Osmoregulation in Fishes: An Introduction). The smolt process involves a suite of physiological, morphological, biochemical, and behavioral changes, which all require sufficient food energy intake as well as efficient energy use. Superimposed on all of this are new predation risks, as there are many animals that feed on young salmon in the new marine environment. All of these factors contribute to the survival bottleneck effect.

Increasing photoperiod in spring seems to be the key environmental factor that synchronizes the endogenous changes occurring seasonally. Long before smolting takes place, individual fry must make a decision as to when they are going to smolt. Most Pacific salmon species complete smolting within a few months after hatching. However, some species such as sockeye wait up 1 or 2 years after hatching. The factors controlling the subsequent downriver migration, however, are not well understood. Current evidence suggests that an innate, endogenous circannual rhythm is the primary controlling factor, one that is trigger by changes in photoperiod. Temperature regulates the rate of physiological processes and is also involved as a modulating factor, just as food availability is. What is clear, however, is that the process of smoltification is directly linked with initiating this migration.

Smolts tend to eat little during the downstream migration. In fact, upon entering the ocean, smolts are often malnourished and in a catabolic state, a condition that is similar to adult salmon during upriver migrations to spawning areas. There is some evidence that the size of the heart increases disproportionately during this time, which may enhance metabolic capacity and efficiency. Although downstream migrants tend to drift passively with the flow, they can and do actively swim, which enables them to attain remarkable migration speeds of 10–20 km or more each day. In river systems, such as in the Columbia River, hydro-electric and other dams can prolong migration by several weeks, and such delays can increase energetic costs and physiological disturbances, thus exacerbating patterns of mortality at a time when mortality is already high (i.e., the survival bottleneck) (**see also Swimming and Other Activities**: Applied Aspects of Fish Swimming Performance).

Smolting is a prerequisite to anadromy and must be regarded an important component of the downstream migration. The associated changes in body shape and metabolism facilitate active downriver migrations, and complex changes to gill, kidney, and intestinal functions occur to optimize ion- and water-exchange systems (**see also Osmotic, Ionic and Nitrogenous-Waste Balance**: Mechanisms of Gill Salt Secretion in Marine Teleosts and Mechanisms of Ion Transport in Freshwater Fishes). The suite of endocrine processes (**see also** The **Hormonal Control of Metabolism and Ionic Regulation**: The Hormonal Control of Osmoregulation in Teleost Fish) that underlie these physiological restructurings for a life in saltwater also have many co-evolved effects of migratory behavior. These include a migratory restlessness, which occurs in the days and nights before downriver migration begins, which is important for initiating the migration, as well as increases in general activity level (i.e., increased metabolic rate). The hypothalamus and possibly the pineal gland likely receive information about environmental light and temperature levels, which provide important information about the time of year (i.e., seasonality), and via the pituitary gland, a cascade of hormones are then released to direct physiology, behavior, and morphology along migratory lines. Hormones also elevate metabolic rate and alter the alertness of the fish to different stimuli, thus bolstering the probability of surviving the many challenges of migration.

Experimental studies have provided clues to the roles of many different hormones. During the pre-migratory season, some species of fry are negatively rheotatic, but experimental treatment with the thyroid hormone (T3) made them positively rheotactic. Thus, the natural surge of thyroxine (T4, a derivative of T3) that occurs prior to downstream migration is likely a key trigger for downstream migration. In addition to thyroxine, growth hormone, insulin-like growth factor, and cortisol are other hormones, which increase during smoltification and contribute to the development of gill chloride cells. Chloride cells on the gills represent the primary site for ion regulation in fish in saltwater (**see also Osmotic, Ionic and Nitrogenous-Waste Balance**: Osmoregulation in Fishes: An Introduction). When fish first enter seawater, cortisol concentrations in the blood increase widely and ion concentrations are temporarily elevated. It is worth noting that not all smolts successfully adapt to seawater. In fact, mortality rates among salmon are generally highest during this migration phase, largely due to osmoregulatory unpreparedness. Furthermore, one important hormone for saltwater preparedness is cortisol, which is also a principal stress hormone (**see also Hormonal Control of Metabolism and Ionic Regulation**: Corticosteroids and **Hormonal Responses to Stress**: Hormone Response to Stress). Though the transition to saltwater is inherently stressful, undue stress or stress beyond some threshold level can provide a conflicting physiological motivation, which can adversely affect migratory behavior and survival. For example, high cortisol could lead to early entry to the marine area, before physiological systems have had a change to fully prepare for saltwater, which would put the smolt at risk of mortality. Moreover, additional stressors can lead to further elevations in cortisol, and fluctuations in hematocrit and ionic status also correlate with mortality. All of this information serves to highlight the sensitivity of smolts to a number of factors during the fresh-to-salt water transition, which ultimately affect migration, survival, and fitness.

Migration to Ocean Feeding Grounds

Pacific salmon undertake directed coastal migrations to seek out rich food sources. Some species congregate in sheltered bays, where they exploit food resources that concentrate as a result of eddies and tidal shear forces. Consequently, their speed of migration varies greatly among species. Thus, salmon migrate from near-coast environments to the open ocean after several months to a year.

Many Pacific salmon feed in the Alaskan Gyre, a productive region of the northeast Pacific Ocean (i.e., Gulf of Alaska). Modeling studies suggest that the swimming speeds required for fish to override the influence of ocean currents in this region are prohibitively costly. Consequently, sockeye salmon, for example, are known to complete two large counter-clockwise loops of the northeast Pacific during 2 years, riding on the Gyre currents, while attaining a mature size and mass prior to homeward migrations. Nonetheless, most of the Gulf of Alaska is considered unfavorable for fish growth based on temperature suitability and prey availability. Salmon prefer cold water, and even small increases in surface water temperatures can dramatically reduce growth potential. To obtain sufficient energy to fuel the homeward migration to natal streams and enable reproduction, salmon in the ocean must feed optimally (i.e., near maximum ration) and continually, searching for zones of positive growth potential. To locate and exploit patchy food resources and areas with optimal thermal conditions, perhaps avoiding areas of high temperature, salmon must have finely tuned physiological systems that enable them to detect and evaluate subtle differences in growth potential conditions. Few physiological studies have been undertaken on Pacific salmon in the high seas to examine these mysteries.

Directed Migration to the Coast and Natal River

Pacific salmon start their impressive migration toward natal streams after 1–3 years of feeding in rich ocean waters. They typically gain about half of their adult mass in their last 6 months at sea and therefore continue feeding as they migrate towards the coast. What triggers salmon to make the decision to initiate homeward migrations is poorly understood, but is presumably linked to reproductive maturation and the endocrine system (**see also Hormonal Control of Reproduction and Growth**: Endocrine Regulation of Fish Reproduction). When researchers manipulate gonadotropin-releasing hormone (GnRH) in salmon, it triggers the growth of gonadal tissue and such growth is associated with a shift from foraging to homing in salmon.

Testosterone is an end-product of GnRH release and this hormone is believed to be the direct link to migration behavior. Masu salmon that were castrated to eliminate testosterone production stopped migrating, but resumed migration when subsequently injected with testosterone. Testosterone also influences the speed at which salmon return to their natal rivers – higher testosterone levels lead to faster swimming into natal rivers. The trigger for initial for GnRH release is likely associated with both exogenous factors such as changing photoperiod (i.e., changing seasons) and endogenous factors such as nutritional condition and body size. It is possible that GnRH will only trigger homeward migrations if fish which exceed certain growth or energetic thresholds. Thus, sometimes some Pacific salmon species vary in their abundance from year to year, sometimes spending an extra year in the ocean (with the exception of pink salmon which have a 2-year life cycle; **see also Hormonal Control of Reproduction and Growth**: Endocrine Regulation of Fish Reproduction and **The Reproductive Organs and Processes**: Vitellogenesis in Fishes).

After triggering a homeward migration, immense navigational challenges ensue as fish must find their way from the Alaskan Gyre to their natal coastal river. Natal homing represents one of the most remarkable characteristics of Pacific salmon migrations and one of the greatest feats of any animal. There is still much debate about the sensory cues and physiological systems used by salmon to direct homeward migration. In general, it is believed that while in the open oceans, salmon should swim with small vertical and horizontal oscillations, which would enable them to sample odors from different water layers. It is believed that salmon are able to recognize four major odorants (amino acids, bile salts, steroid hormones, and prostaglandins) at minute concentrations (**see also Smell, Taste, and Chemical Sensing**: Morphology of the Olfactory (Smell) System in Fishes). Collectively, these odorants from natal streams create what is known as the 'home stream olfactory bouquet', and these are apparently detectable even in the open ocean. Beyond detecting natal odors, salmon must use other sensory systems to help fish move toward natal streams. Vision seems to be of paramount importance for migratory salmon, and they may use a sun compass, polarized light patterns, or even landmarks to guide them homewards (**see also Vision**: Adaptations of Photoreceptors and Visual Pigments and Behavioral Assessment of the Visual Capabilities of Fish). Studies have revealed that even experimentally blind salmon can find their way home, slowed by days of random swimming. Presumably, the fish rely solely on olfactory cues when visual cues are unavailable. Water temperature and salinity levels (i.e., less saline waters) may also serve as orientation cues, particularly as they approach the river mouth.

Physiologically, preparation for transition to freshwater and reproduction also occur during homeward migration. Timing is critical. Salmon must position themselves at the mouth of the river at a time that coincides with an appropriate level of osmoregulatory preparedness and when river conditions such as flow and temperature are suitable for initiating upriver migration. Physiological sampling of fish between 700 and 250 km away from river entry shows that they are pre-prepared for the transition to freshwater well before arrival at the river mouth. For example, gill Na^+/K^+-ATPase, an important ionoregulatory enzyme (**see also Osmotic, Ionic and Nitrogenous-Waste Balance**: Mechanisms of Gill Salt Secretion in Marine Teleosts and Mechanisms of Ion Transport in Freshwater Fishes), is downregulated in preparation for freshwater despite the fish still being in full strength seawater.

In addition, reproductive hormone concentrations are also elevated (**see also Hormonal Control of Reproduction and Growth**: Endocrine Regulation of Fish Reproduction). At some point during this phase, salmon stop feeding, with the exact time and location varying by stock and species.

Adult Upriver Migration to Natal Stream

One of the most conspicuous, well-studied animal migrations is that of the upriver migrations of Pacific salmon. These migrations are perhaps the best known because they present a rare opportunity to visibly see large numbers of salmon, and because the numbers of returning salmon can reach into the millions. The distances that salmon swim to reach spawning areas vary among populations within species, and among species, and can range from as few as 10–100 km to well over 1500 km. At times, salmon must leap over barriers (**Figure 3**). Regardless of the relative difficulty of a migration, energy reserves are limited and must be allocated carefully and conserved wherever possible. Energy stores are needed to fuel migration, complete sexual maturation, and support behaviors and morphological changes associated with courtship and spawning. At the onset of upriver migration, salmon populations differ in their somatic energy store in an adaptive way; long-distance migrants starting the migration with higher somatic energy (their gas tank is fuller for the journey ahead). A trade-off for long-distance migrants is that they have fewer and smaller eggs than short-distance migrants. This type of reproductive trade-off is common in other animals that make arduous migrations. To conserve energy further, long-distance migrants have smaller and more compact bodies making them more hydrodynamic when swimming. Furthermore, because long-distance migrants often encounter more difficult river hydraulics, they typically have a higher maximum metabolic rate.

As in coastal migrations, high testosterone levels are associated with fast river migration speeds, and also with high levels of aggression in spawning fish. Aside from its influence on behavior, testosterone and other sex steroids (e.g., estradiol, 11-ketotestosterone) are responsible for the production of gametes and the development of secondary sexual characteristics – the morphing from a sleek chrome colored ocean salmon into the hooked nosed, humped backed, and brightly colored form found on spawning grounds (**Figure 4**). Gamete production and morphological change generally occur over a period of weeks to months, and reach their peaks toward the end of upriver migration, which is necessary because both processes negatively affect hydrodynamic efficiency in homing salmon. Once migration is finished and salmon are on spawning grounds, swim efficiency is no longer important and spawning forms can be modified for reproductive combat.

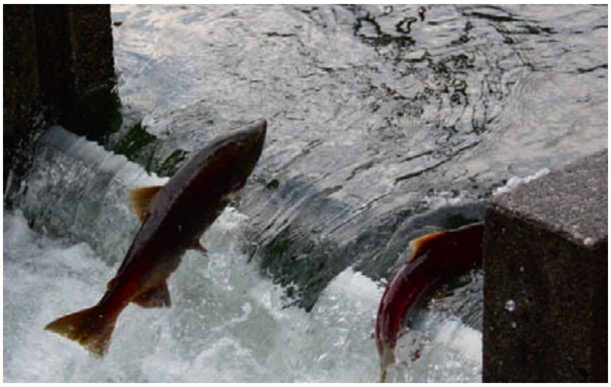

Figure 3 Jumping sockeye salmon en route to spawning grounds. Pacific salmon have remarkable jumping abilities needed to negotiate natural and artificial barriers encountered during spawning migration.

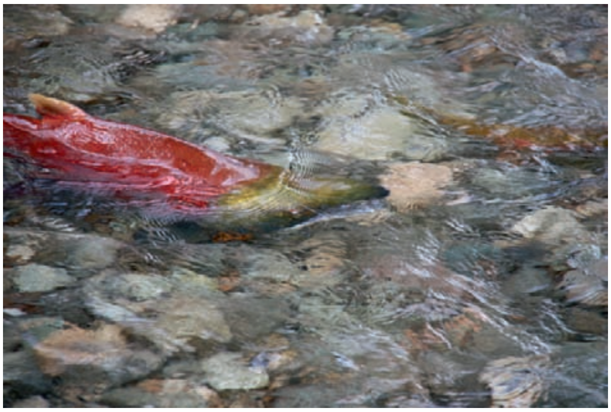

Figure 4 Mature male sockeye salmon on spawning ground. The pronounced hump on the back, curved jaw (known as the kype) and red colouration are reflective of sexually selected traits that are desired by females.

Anthropogenic Threats Involving Salmon Migrations

Because of their migratory life style, Pacific salmon face a myriad of threats to their existence. Barriers to migration represent the single largest problem faced by anadromous Pacific salmon because an inability to physically proceed to a subsequent life stage can, in a short time, extirpate a population. Large dams and associated water diversions to store and divert water for hydroelectricity, agriculture, land reclamation, and human consumption have caused widespread extinctions. For example, in the Columbia River basin, 35% of Pacific salmon stocks are extinct and 40% are endangered. Some dams have been fitted with bypass structures (e.g., fish ladders or fishways; see **Figure 5**) to enable smolts to migrate downstream and adults upstream. Small barriers are also problems. The residential and industrial development has annihilated most salmon in the lower mainland in and around

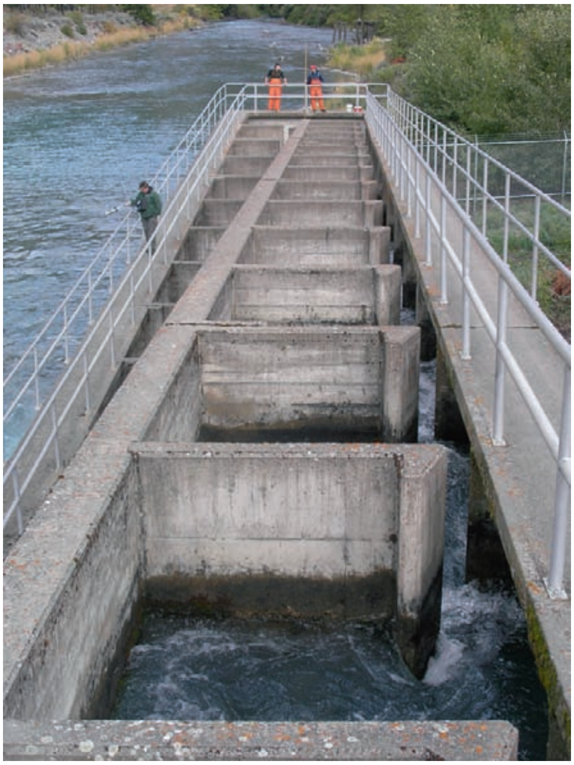

Figure 5 Fish passage facility to enable Pacific salmon to pass a dam in the Fraser River basin. Fish passages (also known as fishways or fish ladders) are engineered structures built to facilitate passage of fish around natural or artificial barriers.

Vancouver and bordering on Canada's greatest salmon watershed, the Fraser River. The most common type of stream crossing in the Pacific Northwest are corrugated pipe culverts which number in the hundreds of thousands on salmon bearing streams. Many have been installed improperly and are undersized resulting in streambed erosion at the downstream end and the culvert outfall perched above the stream thereby isolating upstream areas from downstream ones effectively eliminating adult migrants from many small creeks and streams. The replacement of perched culverts with larger diameter or open natural bottom arch culverts has shown to be an effective response to this problem (**see also Swimming and Other Activities**: Applied Aspects of Fish Swimming Performance).

Mortality can also occur due to physiological stress, delay, and physical injury. Migrations are inherently stressful periods of life, particularly those involving transitions between freshwater and saltwater. Anthropogenic stresses add to this.

Exacerbating these stresses are the environmental challenges associated with climate change. Warming rivers are now pushing some populations of adult salmon beyond their optimal temperature such that they have reduced or no aerobic scope for migration. In addition, disease and illness have become more apparent in these warmer migratory environments affecting spawning fish. Less productive and warmer oceans are reducing growth rates and energy reserves and changing migration timing (**see also Integrated Response of the Circulatory System**: Integrated Responses of the Circulatory System to Temperature and **Temperature**: Effects of Climate Change).

Because adult salmon migrate in high numbers and at predictable locales and times, humans have been able to effectively exploit this resource. For centuries, First Nations relied on salmon for food, trade, and as part of their mythology and spirituality. European settlers established coastal communities in North America, which relied heavily on the fishery. Though overfishing has led to several stock declines in the past, large fisheries still exist today. Depending on the type of fishing gear, large numbers of fish can escape from capture or are released after capture. Though research is limited, stress and delayed mortality of escaped or released fish can be high, especially in warm rivers. Thus, fisheries and a warming climate may put Pacific salmon in a double jeopardy.

Conclusions

Pacific salmon are a relatively well-studied group of animals compared with other fishes, and their migrations have been focus of considerable investigation. Researchers have learned that migrations are a complex interplay of behaviors and physiology, involving an integration of sensory and locomotory systems, mediated by endocrine and osmoregulatory systems. Pacific salmon have also served as key models for addressing questions related to fish orientation, mating systems, and evolutionary biology. Yet, there remain many large gaps in our knowledge. For example, we know relatively little about the biology of Pacific salmon in the ocean. In addition, even what appears as simple questions are difficult to address: e.g., why do some individuals die and some survive migrations, why do all migrants die after spawning? New technology such as the use of biotelemetry transmitters and archival data loggers, and the integration of these approaches with physiological bioassays show promise for illuminating the biology of salmon throughout their lives, but particularly in the ocean. In addition, functional genomics has the potential to dramatically improve our understanding of the physiological basis for different migratory strategies. Given the anthropogenic threats faced by Pacific salmon during their migrations, improving our understanding of the behavior and physiology of their migration will be essential to ensure appropriate management and conservation strategies.

Glossary

Benthic Organisms living on, or near, the seafloor; lowest level of a body of water.

Deep sea Ocean depths greater than 1000 m.

Demersal Pertaining to fish that live near the bottom of oceans and lakes.

Hydrostatic pressure Pressure due to the height of a column of fluid directly above the reference point. This pressure exists in both static and flowing fluids and can be either added to, or subtracted from, the hydraulic pressure, where the reference point is the heart.

Pelagic Pertaining to fish that live in the water column of oceans and lakes.

Swimbladder A gas-filled chamber in the abdominal cavity of most bony fishes. The swimbladder is used in buoyancy control in most species; it also subsumes roles in hearing and sound production in some species.

What Is the Deep Sea?

Seawater covers the majority (71%) of the surface of the Earth (**Figure 1**). The average depth is nearly 4000 m. The deep ocean is characterized as occupying depths greater than 1000 m. Deep-sea fishes are those that occupy these depths for some or part of their life history. At such depths, the hydrostatic pressures exerted on fishes are at least 100 times greater than the atmospheric, plus there is no sunlight to support algal photosynthesis. Remarkably, abyssal depths (3000–6000 m; **Figure 2**) cover 51% of the Earth's surface, resulting in the average ocean depth being 3800 m. Hadal depths (<6000 m) cover only <2% (**Figure 1**). The deepest part of the oceans, the Marianus Trench, reaches over 11 000 m, deeper than the height of Mt. Everest. Water pressure at these extreme depths is more than 1000 times greater than that at the sea surface, and 3000 times higher than on the top of Mt. Everest! Remarkably, fishes live at these extreme depths.

Deep ocean water has a stable, cold temperature. This situation arises because, as seawater cools, its density increases up to its freezing point of about −1.9 °C (freshwater is at its most dense at 4 °C). Therefore, cold seawater tends to sink, taking dissolved oxygen with it. Additionally, when seawater freezes, the ice is virtually free of salt, which results in the remaining water having a higher salinity and density.

The boundary between the bathopelagic and overlying mesopelagic zones is set at 1000 m (**Figure 2**) and is generally viewed as the lower limit for the diel migration of micronekton. In the absence of light, organic matter is mostly transferred down to these depths by sedimentation. With a limitation of organic resource input, the biomass at 1000 m is just 10% of the euphotic zone and a mere 1% at 4000 m.

Remarkably, a zone of maximum species richness exists around 1000 m. Therefore, despite the challenges and constancy of deep water, deep-sea fishes show remarkable diversity, none more appealing than the diverse morphologies that have been described as anything from grotesque to unbelievable. Such was the fascination with the visual appearance of deep-sea fishes that they were used for the frontispiece of the high school textbook produced by Haldane and Huxley in 1927 (**Figure 3**).

Our knowledge of the deep sea and its fishes is limited, but is continuously growing. The limited knowledge base simply reflects immense technological challenges associated with such studies. Fishes brought to the surface

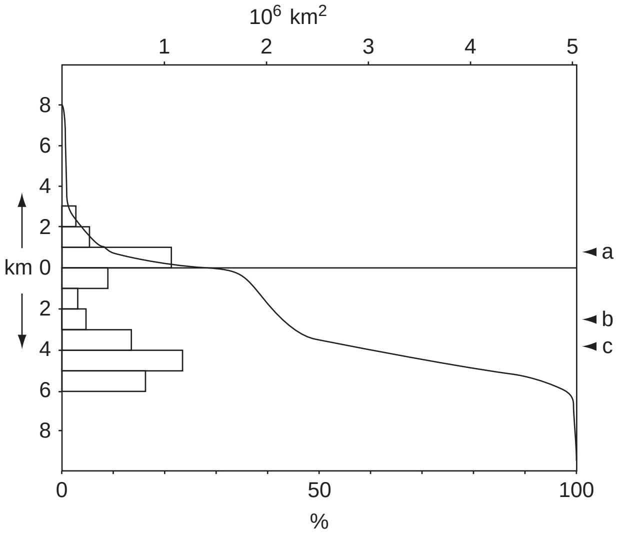

Figure 1 Percentages and areas of the Earth covered by land of various elevations and water of various depths. *a*, mean land elevation (840 m); *b,* mean sphere water depth (2440 m); and *c*, mean ocean depth (3800 m). from a depth may partially disintegrate under reduced surface pressure, that is, if they do not die or get eaten in the trawls that, take several hours to retrieve from such depths. To observe deep-sea animals in their own elements requires sophisticated feats of engineering so that the equipment can withstand extreme hydrostatic pressure and can be remotely operated kilometers away.

The deep sea represents the final frontier of discovery on the Earth. The challenges that scientists must overcome to observe deep-sea fishes are some of the very same ones that deep-sea fishes adapted to during evolution. This article is about some of these remarkable adaptations.

Evolutionary adaptation to the deep sea was not a single event. Deep-sea fishes belong to 22 orders of fishes. Remarkably, 10–15% of the 25 000 or more fish species are found in the deep sea, and more are being discovered every year. Even so, the Perciformes, which radiated so spectacularly in shallow waters, have very few deep-sea representatives. Species diversity decreases with depth beyond the range of 400–2000 m, which is the depth range that has the most diverse species. Some deep-sea fish species have very relatively vertical distributions of a few hundred meters, whereas others such as *Coryphaenoides rupestris* and *Synaphobranchus kaupi* vertically distribute over thousands of meters.

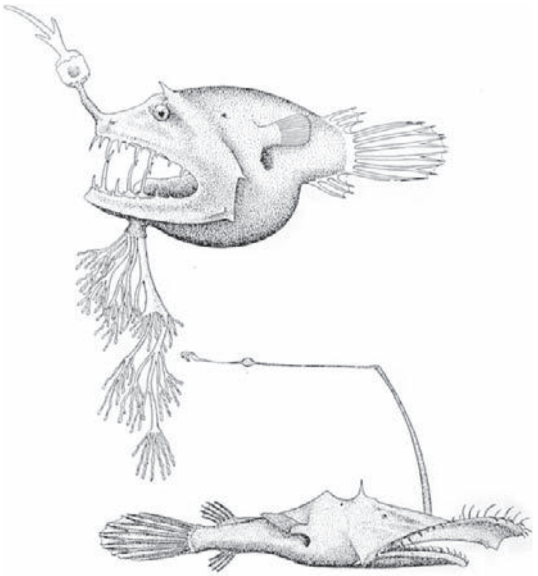

Figure 3 Illustrations of two deep-sea fishes (A. *Linophryne arborifer* and B *Lasiognathus saccostomus*) used in an introductory cover plate for Haldane's and Huxley's 1927 textbook on Animal Biology for high school biology.

Feeding among the Deep-Sea Fishes

Despite the relative constancy of the deep-sea environment, deep-sea fishes show seasonal cycling of reproduction. This is almost certainly tied to seasonal food abundance. Accompanying each spring and summer bloom of primary productivity in the euphotic surface waters of the ocean, comes a rain of sinking dead, organic material, which provides most of the energy input for the deep sea and its fishes.

With a low density of animals, no ambient light, and the need to feed in an environment where the biomass available as energy is less than 5% of that in surface waters, it pays to confuse or be invisible to potential predators. Therefore, deep-sea fishes are remarkably well endowed with effective lures and capture methods for prey (**Figure 3**), as well as visual adaptations and bioluminescence (**see also Vision**: Visual Adaptations to the Deep Sea and **The Skin**: Bioluminescence in Fishes).

Diets range widely from zooplankton, gastropod mollusks, polychaete worms, crustaceans, and gelatinous organisms (such as the salps and larvaceans belonging to the Urochordata) through to fishes. Trying to understand exactly what deep-sea fishes eat using traditional methods of species capture and stomach analysis has been fraught with technical difficulties. For example, few specimens come up in a trawl. Many of the pelagic fishes are small (<300 mm) making both capture and visual observation in submersibles difficult. Large predators often have empty stomachs. Over-inflated and everted swimbladders may empty the stomach. Of course, opportunistic feeding within a trawl net for several hours could cause bias. In addition, soft-bodied and gelatinous prey are difficult to identify.

The jaw and gill morphology provide good clues to food habits. Ambush predators are characterized by a large jaw equipped with numerous long, sharp, and depressible teeth. Short gill rakers point to piscivory, whereas long, closely set rakers suggest small prey items. A simple, short, straight gut likely indicates that large prey is ingested as a whole.

Some benthic deep-sea fishes actively forage; they arrive within minutes at baited cameras placed at a depth. They likely use odors to locate the bait (**see also Smell, Taste, and Chemical Sensing**: Chemoreception (Smell and Taste): An Introduction). These species include the abyssal macruourids, chimaeras, morids, synaphobranchids, and sharks. Ultrasonic transmitters placed on fishes similarly support the importance of active foraging among deep-sea fishes, rather than just sit-and-wait predation. All the same, the species that are seen at baited cameras may not be the same species caught by trawl in the same region, clearly suggesting that not all deep-sea fishes are active scavengers.

Trophic guilds are used to characterize a fish's feeding habit. For the demersal deep-sea fishes, several hundred species are assigned to 10 trophic guilds.

Guild 1: Piscivores that often have large teeth and lures. Included are subguilds for sit-and-wait predators (the lizard fish *Bathysaurus ferox*) and for active predators (the large macroruids of the genus *Coryphaenoides*).

Guild 2: Macronektonic foragers (macroruids of the upper and middle slopes such as *C. rupestris* and *Bathygadus melanobranchus*). These fishes may be found in schools and have large, well-developed gill rakers. Bioluminescence may be used to communicate.

Guild 3: Micronectonic/epibenthos predators (the morid *Lepidon eques* and the macroruid *Coelorhinchus coelorhinchus*). These abundant dermersal species likely use olfaction, tactile sense, and lateral line sense to detect prey.

Guild 4: Benthivorous infaunal predators (e.g., members of the eelpout family) that eat mollusks and polychaetes. Few deep-sea species use this feeding habit.

Guild 5: Microphagous epifaumal browsers (species of the genus *Polycanthonotus*). They use a slender snout and ventral mouth to feed on small benthic crustaceans and polychaetes.

Guild 6: Megafaunal croppers and browsers. A few species such as *Notacanthus chemnitzi* selectively crop anemones, corals, and bryozoans.

Guild 7: Macroplanktonivores (slickheads such as *Conocara fiolenti*). These feed on slow-moving gelatinous prey, and may drift themselves.

Guild 8: Specialist necrophages (*Synaphobranchus kaupii* and hagfishes). These fishes are strongly attracted to baited traps.

Guild 9: Necrophagivores (*Paraliparis bathybius*). These fishes are often gelatinous themselves.
Guild 10: Detritivores (*Conocara macropterum*).

The deep-sea pelagic fishes are assigned to three trophic guilds.

Guild 1: Micronecktonivores are either active foragers, with a large mouth, teeth and stomach, or sit-and-wait predators that typically use lures. The *Ceratioidei* families belong to the piscivorous subguild and *Crytopsarus couesi* belongs to the cephalopod mollusk predators.
Guild 2: Zooplanktivores typically have numerous fine teeth (members of the family Nemichthyidae).
Guild 3: Generalists (the bathypelagic gulper eel family Eurypharyngidae).

Effects of Pressure

Deep-sea fishes face immense hydrostatic pressure, at least 100 times and up to 1100 times greater than that experienced at the sea surface. Such high pressures have important consequences to buoyancy and to basic biochemical reactions.

Buoyancy

Fishes tend to sink in seawater (**see also Buoyancy, Locomotion, and Movement in Fishes**: Buoyancy in Fishes). This is because most of their tissues are denser than seawater ($\sim$1.026 kg L^{-1}). The two solutions used to solve this problem involve resting on the benthos for benthic fishes and continuous swimming for pelagic fishes. In addition, fishes in general have evolved mechanisms make their bodies neutrally buoyant, allowing them to avoid the energetic cost of continuous swimming or a benthic life. Therefore, adaptations for neutral buoyancy among deep-sea fishes are to be expected, especially given the limitation on energy resources in deep sea.

Fishes, as a whole, use three primary strategies to attain neutral buoyancy (**see also Buoyancy, Locomotion, and Movement in Fishes**: Buoyancy in Fishes).

1. They use lipids to lower their overall density.
2. They use a swimbladder (**see also Buoyancy, Locomotion, and Movement in Fishes**: Swimbladder Function and Buoyancy Control in Fishes) to lower their overall density.
3. They decrease the amount of high-density tissue such as bone (1.3–1.5 kg L^{-1}) by either decreasing the size or thickness, or reducing the mineral content (e.g., calcium).

All three strategies are in evidence in deep-sea fishes, although the last strategy is relaxed for benthic species, especially ambush predators that need large jaws and teeth.

Swimbladder

A gas-filled chamber called a swimbladder can account for 5–6% of the size of certain fishes. While this added volume increases the drag of a fish when it moves through water, it is a very effective means of achieving neutral buoyancy because of the large difference in density of water and air. Even so physiological specializations are required to deposit gases into the swimbladder (**see also Design and Physiology of Arteries and Veins**: The Retia, **Buoyancy, Locomotion, and Movement in Fishes**: Swimbladder Function and Buoyancy Control in Fishes, **Transport and Exchange of Respiratory Gases in the Blood**: Root Effect: Molecular Basis, Evolution of the Root Effect and Rete Systems, and Root Effect: Root Effect Definition, Functional Role in Oxygen Delivery to the Eye and Swimbladder) and to remove them, should the fish rise in the water column (otherwise the fish become positively buoyant as the gas expands under reduced pressure).

Gas-filled swimbladders are found in deep-sea fishes to depths of 5000–7000 m (e.g., myctophids). At these depths, the density of gases is greatly increased (0.6–0.7 kg L^{-1}) compared with the surface, but a substantial difference still remains relative to the density of seawater (1.027 kg L^{-1}). Oxygen is the primary gas found inside the swimbladder of deep-sea fishes. It is thought that a depth limitation exists for the swimbladder that is related to the ever-decreasing ability to unload gas from hemoglobin and into the swimbladder using the Root effect as fish move deeper. One suggestion is that a total pressure of 10 atm is the upper limit for gas deposition, but others suggest 140 atm. Furthermore, the walls of the swimbladder must have a greater gas impermeability compared with shallow-water teleosts because of the higher partial pressure of the gases they are containing.

Lipid inclusions

Deep-sea fishes include lipid deposits in their swimbladders as well. Lipids are typically less dense (0.78–0.93 kg L^{-1}) than seawater and only increase in density by about 1% per 100 atm. While they are denser than gas, they are not subject to volume changes if a deep-sea fish migrates vertically. Unlike the swimbladder of *Coelacanth latimeria*, which is completely filled with wax esters, mid-water deep-sea fishes, such as *Antimora rostrata*, have sheets of bilayered membranes, which have a high cholesterol content. Paradoxically, cholesterol has a higher density (1.067 kg L^{-1}) than seawater, but it offers the advantage of a high oxygen solubility, which may aid oxygen deposition to and retention in the swimbladder at high ambient pressure.

High concentrations of lipids are found in sharks (**see also Buoyancy, Locomotion, and Movement in Fishes**: Buoyancy in Fishes and **Chondrichthyes**: Physiology of Sharks, Skates, and Rays) and *C. latimeria*, especially in the liver. Eggs of deep-sea fishes (e.g., *Macropodus opercularis* and *Ophiocephalus argus*) also use oil droplets to achieve neutral buoyancy.

Watery Fluids and Gelatinous Tissues

Because muscle is denser (1.05–1.07 kg L^{-1}) than seawater, some deep-sea fishes compensate by reducing their muscle mass (which necessarily reduces locomotory ability), whereas others have watery muscles, for example, *Acanthonus armatus*. The gelatinous tissues of *Bathylagus* species have an extremely high water content (96% vs. a more typical 80%), likely aided by the inclusion of hygroscopic glycosaminoglycans. Although plasma is already less dense than seawater, *A. armatus,* for example, has hypoosmotic fluids that have reduced concentrations of sodium to decrease its plasma density to 1.008 kg L^{-1}.

Biochemical Structures and Reactions

Exposure of shallow-water fishes to high pressure typically results in hyperactivity, convulsions, torpor, and even death. Some of these responses occur at pressures as low as 50 atm, well below the pressures routinely experienced by deep-sea fishes. Knowledge on the pressure tolerance is limited, but some of this tolerance must lie at the biochemical level of biological organization.

Pressure exerts its effects through volume changes. Application of pressure shifts chemical equilibria to a lower volume. Therefore, pressure will tend to disrupt three-dimensional structure, which is often so critical for the proper functioning of biological molecules, such as proteins, and biological membranes, which are crucial for regulating the internal environment of all cells. For example, most enzymes are inhibited at high pressure. However, this inhibition is not a result of protein denaturation, at least in the pressure range experienced by deep-sea fishes.

Proteins

Studies on protein function for deep-sea fishes are limited in number. However, findings for the ubiquitous and highly expressed structural protein actin illustrate a more general finding deep-sea fishes evolved pressure-insensitive forms of proteins and enzyme, rather than forms that tolerate a specific range of high pressure.

F-Actin is a polymer of the G-actin monomer found in most cells, and the volume change that accompanies polymerization, therefore, should be pressure sensitive. This is certainly the case for actin isolated from the shallow-water *C. acrolepis*, where the volume change is 60 mL mol^{-1}. (Volume changes may be twice as high as this value for polymerization of actins isolated from terrestrial species.) By contrast, polymerization of actin isolated from *C. armatus*, which occurs at depths of 2000–5000 m, is little affected by pressure, likely because the volume change associated with polymerization is considerably smaller (<10 mL mol^{-1}). The reason for this pressure insensitivity is unclear, but it may be related to relative incompressibility of the G-actin monomer.

The tetrameric enzyme lactate dehydrogenase provides another example of pressure insensitivity among deep-sea fish proteins. Enzyme isolated from the deep-sea *Sebatolobus altivelis* and the shallow-water S. *alascanus* had identical kinetics when tested at atmospheric pressure. However, the concentration of one of its substrates (NADH – nicotinamide adenine dinucleotide) to produce half the maximal rate was doubled at 70 atm for *S. alascanus* and continued to increase up to 200 atm. By contrast, the required concentration for *S. altivelis* increased by only 33% at 70 atm and no further at higher pressures. Maximum activity of this enzyme was unaffected by pressure, independent of the species being tested. Similar results for these two fish species were found for the isolated enzymes glyceraldehyde 3-phosphate and malate dehydrogenase. Likewise, the signal transduction enzyme, adenylyl cyclase, isolated from *A. rostrata* was pressure insensitive. The molecular basis of pressure insensitivity is still being studied.

Cell membranes

The composition of cell membranes is also altered to compensate for lateral compression at high pressure. Compression would have made the membrane less fluid, similar to the overall effect of cold temperature (**see also Temperature**: Effects of Temperature: An Introduction and Temperature and Excitable Membranes). In fact, the effect on membrane fluidity of 11 000 atm at 4 °C is equivalent to that at −20 °C at atmospheric pressure. Not surprisingly, cell and mitochondrial membranes of deep-sea fishes show increased content of unsaturated fatty acids to reduce their fluidity, just like cold-adapted and cold-acclimated animals. Such changes have already been shown to be important for the function of membrane-bound proteins. For example, lipid substitution in membranes has revealed that at least a part of the pressure insensitivity of the enzyme Na^+/K^+-ATPase of a deep-sea fish is due to increased membrane fluidity.

Metabolic rate

A curious and unexplained aspect of deep-sea fishes is their low metabolic rate. It is reported that metabolic rates of deep-sea species found at 1000 m or below can be 10 to 15 times lower than surface species. Such large differences cannot be attributed to the relaxed selection for locomotion and the sit-and-wait predatory lifestyles. Nor can they be explained by reduced enzyme concentrations in the muscle tissue. While low temperature is an obvious contributing factor to low metabolism, other factors must feature. One possibility is that protein turnover rates are much lower in deep-sea fishes. While protein synthesis can represent

30% of metabolic rate in surface fishes, such determinations have not been made in deep-sea fishes.

Summary

Many species independently evolved to take advantage of the deep-sea environment, despite the challenges of extreme pressure, cold temperature, absence of light, and very low energy input. To do so, they have adopted a wide range of feeding habits, showing extreme morphological and physiological adaptations to both lure prey and avoid being captured. Their protein structure, cell membrane composition, metabolic rates, and buoyancy mechanisms appear to be well adapted for life at high pressure, cold temperature, and limited food. Nevertheless, much remains to be discovered for this fascinating group of fishes, provided the technical challenges for studying deep-sea fishes can be overcome.

Glossary

Abiotic factors Nonliving chemical and physical factors in the environment (e.g., temperature and salinity).
Compatible solutes A variety of organic compounds (including sugars, polyols, amino acids, and their derivatives) that animals use to balance their internal osmolarity relative to external osmolarity without disrupting cellular functions. Also known as osmoprotectants.
Estuary A partially enclosed body of water formed where freshwater from rivers and streams mixes with seawater as the tides advance and recede.
Euryhaline Animals that physiologically adjust to a wide range of water salinity are considered euryhaline (eury 'broad'; haline 'salt'), in contrast to stenohaline animals.
Eurythermal Able to live over a wide range of temperatures.
Hypoxia Low partial pressures of oxygen in external or internal environments.
Hyperoxia Higher than normal partial pressure or content of oxygen in the external environment.
Mangrove swamp Coastal wetlands of tropical and subtropical regions (from ~25° N to 25° S) dominated by salt tolerant shrubs and trees, often (but not exclusively) mangroves of the genus *Rhizophora*.
Normoxia Normal oxygen partial pressure or content in the external environment. For aquatic systems, this is generally around 130 mmHg or similar to the oxygen content of air-saturated water at a particular temperature, salinity, and atmospheric pressure.
Osmolarity The total concentration of osmotically active particles in a solution.
Oxyconformer Organisms that allow their metabolic rate to fall as the environment becomes progressively hypoxic.
Oxyregulator Organisms that maintain their metabolic rate as the environment becomes progressively hypoxic.
Saltmarsh A shallow brackish or saltwater intertidal habitat dominated by salt-tolerant grasses and shrubs.
Stenohaline Describes an organism that cannot live in environments that undergo large changes in salinity.
Stenothermal Describes an organism that cannot live in environments that undergo large changes in temperature.
Vertical zonation A pattern observed in rocky intertidal habitats where different communities of animals, plants, and algae are found at different tidal heights, forming distinctive horizontal bands.

Introduction

Intertidal habitats are not only among the most productive in the world, but also among the most challenging for the fishes that live there. As the name suggests, these habitats are found in areas that are 'between the tides'. Because they are subject to the influence of the tides, intertidal habitats are highly variable in both space and time, and undergo large changes in a host of abiotic environmental variables including temperature, salinity, and oxygenation. In addition, fishes living in these habitats can be exposed to extremely turbulent water flows and may be periodically exposed to air as the tides recede. Because of their coastal location, intertidal habitats are also strongly impacted by human activities and can experience high levels of pollution due to urban or agricultural uses.

Tidal Cycles

Tides, the rhythmic rise and fall of sea levels, result from the competing actions of centrifugal force from the Earth's rotation and the gravitational forces of the Earth and the Sun. In most places on Earth, tides are semidiurnal, with two high tides and two low tides each day (**Figure 1**(**a**)). Semidiurnal tides are common on the Atlantic coast of North America, Europe, and Africa. There are a few locations (such as the Gulf of Mexico and parts of Southeast Asia) where tides are diurnal, with a single high tide and low tide each day (**Figure 1**(**b**)). Mixed tides, in which there are two high tides and two low tides each day each having a different magnitude, are common on the Pacific coast of North America (**Figure 1**(**c**)). **Figure 2** shows the distribution of these different kinds of tides around the globe.

The height of the tide varies depending on the phase of the Moon, the relative positions of the Moon and Sun, and among locations. Approximately twice each month, the Earth, Moon, and Sun align. At these times, which occur shortly after the new moon, the gravitational effects of the Moon and Sun reinforce each other and cause a higher high tide and a lower low tide. These recurring tidal extremes are called spring tides. The most modest tides, which occur when the Moon and the Sun are at 90° relative to the Earth, are called neap tides. Neap tides occur just after the first and last quarter moons. Although the heights of spring and neap tides differ within any given location, this variability is small relative to the huge differences in tidal heights in different locations around the globe. The difference in height between high tide and low tide (or the tidal range) can be as small as 0.3 m in some parts of the Mediterranean Sea to as great as 17 m in the Bay of Fundy, between Nova Scotia and New Brunswick on the Atlantic coast of Canada and in Ungava Bay on the Arctic Coast of Quebec in Northern Canada.

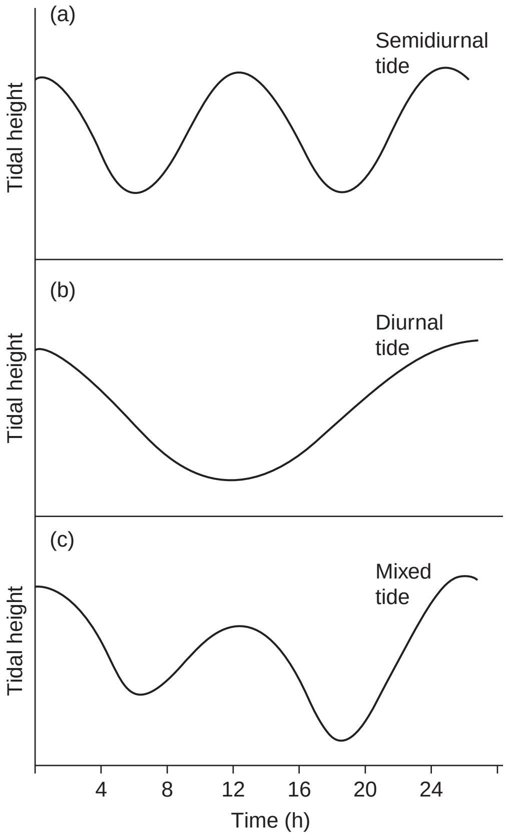

Figure 1 Types of tides. Semidiurnal tides (a) have two high tides and two low tides each day. Diurnal tides (b) have one low tide and one high tide each day. Mixed tides (c) have two high tides and two low tides each day, but their magnitude differs.

Types of Intertidal Habitats

Intertidal habitats include rocky shores, mudflats, salt marshes, and estuaries. The various types of intertidal habitats can be distinguished based on the substrate over which they occur (such as rock, mud, or sand). Rocky intertidal habitats are found in wave-swept areas, where there is sufficient turbulence to prevent sediments from accumulating on the rocky substrate. Rocky intertidal habitats are often steeply sided so the rise and fall of the tides result in a vertical gradient of the amount of time that an area spends out of the water. At the high end of the rocky intertidal, animals may be exposed to air through much of the tidal cycle, whereas at the low end of the rocky intertidal, animals may be submerged in seawater for much of the time. These differences in emersion time result in extreme differences in abiotic conditions over as little as a few meters of vertical distance. In the high intertidal, animals must cope with large changes in abiotic factors such as temperature, salinity, and oxygenation, whereas abiotic conditions are much less variable in the low intertidal. This difference in the variability of abiotic factors between the low and the high areas of the rocky intertidal results in a phenomenon known as vertical zonation (**Figure 3**), that is characterized by distinct horizontal bands composed of different communities of organisms that have different ranges of tolerance. For example, many fishes that live in the low intertidal zone are incapable of surviving the harsh conditions of the high intertidal, and only a few species of fishes are specialized for the extreme conditions of the very high rocky intertidal.

Most soft-substrate intertidal habitats occur in estuaries. The word estuary is derived from the Latin word *aestus*, meaning tides. An estuary can be defined as a partially enclosed body of water formed where freshwater

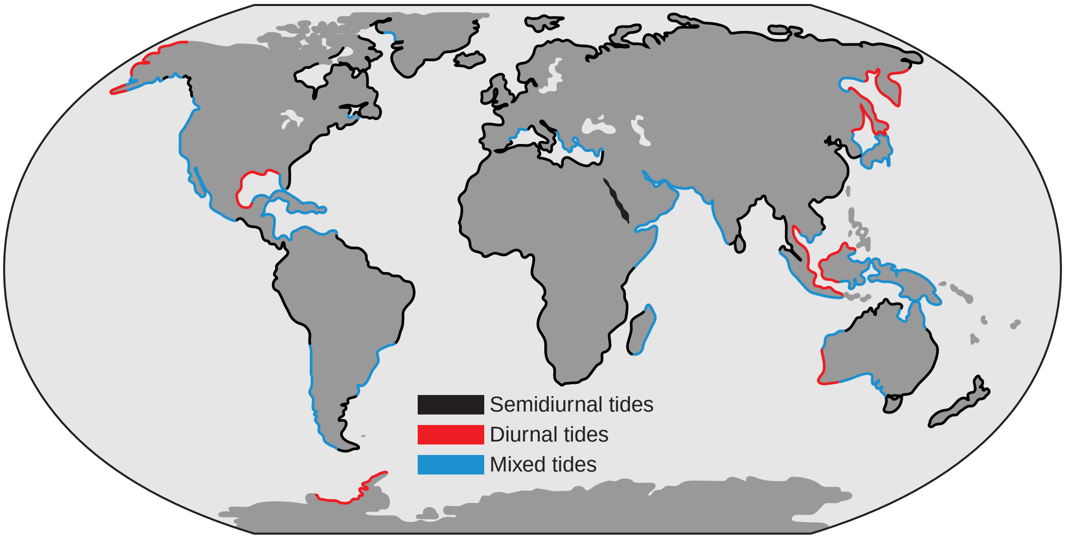

Figure 2 Global distribution of tidal types.

from rivers and streams mixes with seawater as the tides advance and recede. The substrate in an estuary is generally soft, because estuaries are typically sufficiently protected from the direct action of ocean waves to allow sediments to accumulate on the bottom in the form of mud or sand. Estuaries can be divided into a variety of sub-habitats. At the river end of the estuary, there is a zone that is not directly influenced by saltwater, but is indirectly influenced by the tides as incoming saltwater from the tides pushes the freshwater of the river upstream. Thus, these areas have an intertidal zone in which animals can be alternately submerged in freshwater or emerged in air, or in which animals are exposed to changing conditions of water flow. The middle portions of estuaries are generally submerged throughout the tidal cycle, but undergo substantial changes in salinity as seawater moves in and out of the estuary and mixes with freshwater as the tides advance and retreat. In temperate zones, these regions typically consist of a complex patchwork of salt marshes and mudflats (**Figure 4**). Salt marshes have a soft substratum, but have conditions that are suitable for the establishment of plants such as marsh grasses. Salt marshes can be important habitats for juvenile fish. In tropical regions, marsh grasses are replaced by mangroves, forming a mangrove swamp. Mudflats are areas with soft substrates that lack vascular plants, and are instead coated with blue-green algae and diatoms.

Mudflats, salt marshes, and mangrove swamps can be high in hydrogen sulfide (H_2S), a colorless, but extremely strong-smelling gas that is produced by sulfate-reducing bacteria that live in the anoxic regions of the sediment. This gas gives these habitats their characteristic 'rotten egg' smell. Hydrogen sulfide is extremely toxic because it binds tightly to iron molecules. It thus binds to and disrupts the function of critical molecules such as hemoglobin and the mitochondrial cytochromes,

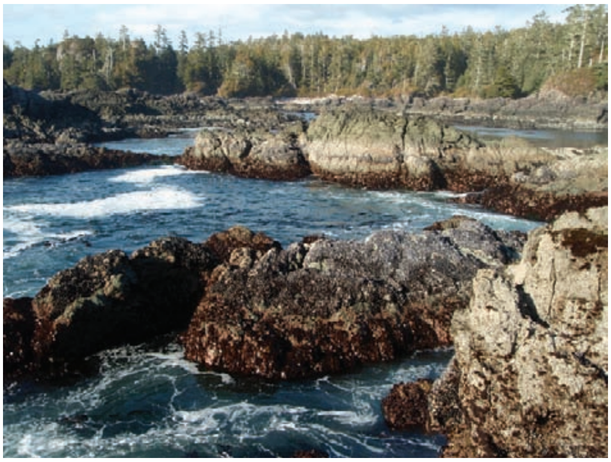

Figure 3 Vertical zonation in the rocky intertidal near Ucleulet, British Columbia, Canada. Photograph courtesy: Dr. Chris Harley.

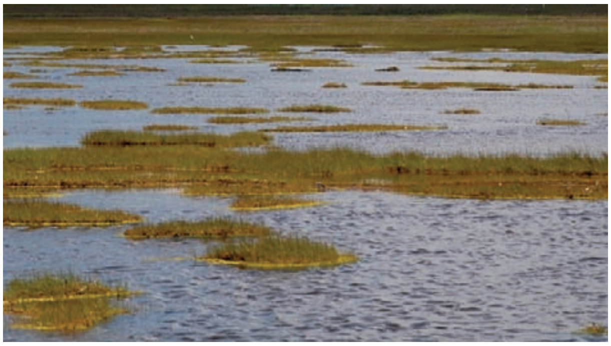

Figure 4 A salt marsh on the Atlantic coast of North America near Tuckerton New Jersey, USA. Photograph courtesy: Kristen Haakons.

preventing both oxygen delivery and oxygen utilization. In fact, hydrogen sulfide is even more toxic than cyanide, and can cause 50% inhibition of cytochrome oxidase at concentrations as low as $1\,\mu\mathrm{mol\,L}^{-1}$. Many mudflat and mangrove swamp fish remain on the surface of the sediment and so are not exposed to toxic levels of this gas. However, some mudflat fishes, such as gobies, dig burrows deep into the mud, which can result in exposure to appreciable concentrations of hydrogen sulfide. For example, hydrogen sulfide levels in the burrows of goggle-eyed mudskippers (*Boleophthalmus boddaerti*), a mangrove swamp goby, can be as high as 0.3 mM. This species possesses efficient mechanisms for detoxifying hydrogen sulfide within its tissues. In contrast, other mangrove swamp dwellers, such as the mangrove killifish (*Rivulus marmoratus*), will typically emerge from water into air when they encounter high levels of hydrogen sulfide.

Adaptations to Changing Salinity

Salinity is the term used to describe the total concentration of dissolved salts in water. Biologists and oceanographers typically express salinity in units of parts per thousand (ppt), which roughly translates to the number of grams of salt per liter of water. Full-strength seawater has a salinity of approximately 35, while distilled water has a salinity of 0. The salinity of the water in intertidal habitats can vary from that of full-strength seawater at high tide to that of nearly freshwater when there is substantial input of freshwater from rivers, streams, or rainwater. Intertidal habitats can even become hypersaline (more salty than seawater) as a result of evaporation of water in isolated pools at low tide.

Changes in salinity are extremely challenging to animal life because the salt concentration of the external medium affects the distribution of water across cell membranes. When in freshwater, fish tend to gain water and lose ions as a result of passive movements along concentration gradients, which must be compensated for through active ion uptake across the gills and intestine (**see also Osmotic, Ionic and Nitrogenous-Waste Balance**: Mechanisms of Ion Transport in Freshwater Fishes). When in saltwater, fish tend to lose water and gain ions, which must be compensated for by drinking and active ion extrusion (**see also Osmotic, Ionic and Nitrogenous-Waste Balance**: Mechanisms of Gill Salt Secretion in Marine Teleosts). Thus, fish must use very different osmoregulatory mechanisms when in freshwater and in seawater. In fact, most fish are stenohaline, and are unable to alter their osmoregulatory mechanisms when experimentally transferred between freshwater and saltwater. Only a relatively small number of fish species are euryhaline and can survive and thrive across a range of salinities. Because of the changing salinities that are characteristic of intertidal habitats, most intertidal fishes are euryhaline.

Most elasmobranchs are stenohaline marine species with an extracellular fluid and cytoplasm osmolarity similar to that of seawater by retaining the compatible solutes urea and trimethylamine oxide (TMAO; **see also Chondrichthyes**: Physiology of Sharks, Skates, and Rays). Only 13 species of truly euryhaline elasmobranchs are known (there are about 35 species of obligate freshwater elasmobranchs and about 100 species that can enter brackish water for brief periods). Euryhaline elasmobranchs allow their body osmolarity to fall from ~1000 mOsM in seawater to ~600 mOsM in freshwater by decreasing urea retention. Note, however, that plasma osmolarity remains substantially higher than the osmolarity of the external medium, and thus euryhaline elasmobranchs in freshwater will tend to passively gain water, which must be removed by producing large amounts of dilute urine.

In contrast, teleost fishes are osmoregulators that maintain their tissue osmolarity relatively constant independent of environmental osmolarity. Although limited data are available for intertidal fishes, it has been suggested that these species have low gill and/or skin permeability to water and ions, which would reduce the costs associated with osmoregulation in a changing environment. In addition, at least some intertidal and estuarine fish, including mudskippers and killifish, are capable of rapidly (30 min to 3 h) and reversibly remodeling the structure of their osmoregulatory tissues in response to changes in external salinity, and changing the way that ions are transported across these tissues on very short timescales, which may help these species cope with their fluctuating environments.

Adaptations to Changing Oxygenation

The level of oxygen in water is typically described using the terms normoxia, hypoxia, and hyperoxia. Normoxic waters are air-saturated and have a partial pressure of oxygen of approximately 130 mmHg. Hypoxic waters have lower oxygen partial pressures, while hyperoxic waters have higher partial pressures. At high tide, rocky intertidal habitats have oxygen concentrations that are similar to the nearby seawater, and are generally normoxic or slightly hyperoxic. In contrast, at low tide, rocky intertidal habitats can have exceptionally variable oxygen partial pressures, particularly high in the rocky intertidal, where the pools are cut off from ocean water for long periods of time (**Figure 5**). During the day, when algae are photosynthesizing and producing oxygen, oxygen partial pressures in the water can exceed 400 mmHg (or 400% air saturation). In contrast, at night, when algae and other intertidal organisms are respiring, oxygen partial pressure

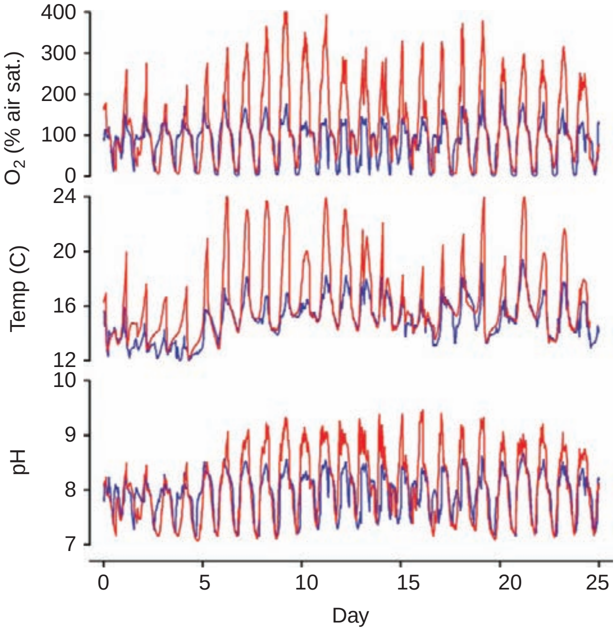

Figure 5 Variation in oxygen, temperature, and pH in tidepools in Bamfield, British Columbia, Canada, at two tidal heights during the tidal cycle. Red lines are data for a high intertidal pool. Blue lines are data for a low intertidal pool. Data courtesy of Dr. Jeffrey Richards.

can drop to near zero. Similar fluctuations in oxygenation occur in salt marshes and mangrove swamps.

Relatively little is known about the behavioral and physiological responses of intertidal fishes to hyperoxia, although hyperoxia is known to cause reductions in ventilatory rate and increases in the production of oxygen-free radicals and free-radical scavenging enzymes such as glutathione peroxidase. In contrast, responses to aquatic hypoxia have been studied intensively in intertidal fishes. Fishes can be divided into two broad groups with respect to their responses to aquatic hypoxia. Oxyconformers allow their metabolic rate to fall as environmental oxygen decreases. Oxyregulators maintain their metabolic rate more or less constant as oxygen falls up to a point called the critical oxygen tension (P_{crit}), when metabolic rate starts to decline. Note, however, that these two groups represent the extreme ends of a spectrum of strategies, and different species of intertidal fish vary greatly in terms of the types of strategy utilized. Whatever the strategy utilized, fishes found in the high intertidal on rocky shores, and fishes that live in salt marshes are typically extremely resistant to environmental hypoxia.

One particularly interesting adaptation to low oxygen that is observed in intertidal fish is that of air breathing or aerial emergence. Intertidal fish exhibit a variety of strategies for air breathing and emergence. Some fish remain submerged, but skim oxygenated water from just below the surface where oxygen has diffused into the water from the air. This strategy is known as aquatic surface respiration (ASR) (**see also Behavioral Responses to the Environment**: Behavioral Responses to Hypoxia). A fish performing ASR still ventilates its gills with water, but takes advantage of a more oxygenated microenvironment within a generally hypoxic zone. Many species of intertidal and estuarine fish exhibit increases in ASR behavior as oxygen tensions in the water decline. Some intertidal fishes are capable of efficiently extracting oxygen from air, and can even maintain metabolic rates in air as high as those seen when the fish are in the water. Unlike many freshwater air-breathing fish, however, most intertidal air-breathing fish do not have specialized air-breathing organs (**see also Air-Breathing Fishes**: The Biology, Diversity, and Natural History of Air-Breathing Fishes: An Introduction). Instead, most intertidal species rely on gas exchange across the gills or skin when respiring in air, and may also use the buccal or opercular cavity, or possibly the stomach.

Air-breathing intertidal fish utilize one of the two main behavioral strategies associated with air breathing. The so-called remainers do not actively emerge into the air. Instead, these species simply allow themselves to be stranded in air as the tide recedes. At low tide, these fishes can be found in moist areas under rocks or seaweed, where they are protected from desiccation. In contrast, active emergers intentionally crawl out of the water when it becomes hypoxic or otherwise inhospitable. The champions of this strategy are the mudskippers (family Gobiidae) and the rockskippers (family Blennidae). These species spend a substantial amount of time out of the water (**see also Air-Breathing Fishes**: The Biology, Diversity, and Natural History of Air-Breathing Fishes: An Introduction). For example, mudskippers feed and even engage in territorial displays when out of water. Mudskippers have a number of behavioral, anatomical, and physiological adaptations that allow them to function well in air. They have muscular fins that allow them to crawl or leap along the ground and unusually thick gills, which are stabilized to prevent the fine secondary lamellae from collapsing when the fish is in air. These thick gills, however, decrease the fish's ability to extract oxygen from the water, and may decrease their ability to survive if trapped below the surface in hypoxic water. As a result, the adaptations that allow these fish to function well in air also tend to cause them to emerge from the water sooner than do other fish species when water becomes progressively hypoxic. Some species of mudskipper will trap bubbles of air in their enlarged opercular cavities to allow them to remain submerged in hypoxic water (**see also Air-Breathing Fishes**: Circulatory Adaptations for Air-Breathing Fishes).

At high tide, many species of mudskipper retreat into burrows in the mud, and the water in these burrows can be quite hypoxic. Mudskippers maintain one or more air chambers within their burrows, which they supply with air from the surface (carried down in their large opercular chambers). Mudskippers place their eggs in these air chambers, allowing the eggs to develop in a high oxygen environment. When the eggs are ready to hatch, the male mudskipper (which guards the burrow) floods the air chamber with water. This submergence induces the eggs to hatch. Aerial incubation of the eggs is a common feature in intertidal fishes. For example, the salt marsh-dwelling common killifish (*Fundulus heteroclitus*) lays its eggs in mussel shells or at the base of seagrasses at the extreme high tide of the tidal cycle (i.e., the spring tide). The subsequent tides of the tidal cycle are not as high, so the eggs incubate in air. At the next spring tide, the eggs are submerged, and the drop in oxygen associated with submergence acts as a cue to cause the eggs to hatch.

Adaptations to Changing Temperature

In most intertidal zones, seawater temperatures are relatively stable throughout the year and from day to night compared with the potentially highly variable temperatures of freshwater and aerially exposed habitats. Thus, fishes living high in the rocky intertidal or in the freshwater/seawater mixing zone of estuaries can be exposed to extremely large temperature changes during a tidal cycle. **Figure 5** shows the temperature changes in tidepools at various heights in the rocky intertidal on Canada's Pacific Coast. Change in temperature can have profound effects on the physiology of ectotherms such as fish (**see also Temperature**: Effects of Temperature: An Introduction), in the absence of physiological specializations to cope with these fluctuations. As a result of the variable nature of their habitat, intertidal fish are remarkably eurythermal (able to cope with a wide range of temperatures). For example, the common killifish, *F. heteroclitus*, which is found in salt marshes along the east coast of North America, can be acclimated to temperatures ranging from ~2 °C to over 30 °C, and can tolerate abrupt changes in temperatures (e.g., from 5 °C to 33 °C, or even up to 37 °C, if the temperature ramps up gradually over the course of an hour or so). The role of heat shock proteins in protection from high temperatures (**see also Temperature**: Heat Shock Proteins and Temperature) has been intensively studied in several species of intertidal fish. Some species of intertidal fish appear to maintain unusually high levels of the constitutively expressed heat shock protein hsc70, which may serve to protect cellular functions against acute heat stress.

Other Environmental Factors

In addition to changes in salinity, oxygenation, and temperature, intertidal habitats also undergo changes in CO_2 and pH through the tidal cycle (**Figure 5**). In the confined environment of a tidepool, or within the burrow of a mudflat fish, respiration by animals, plants, and algae can cause large increases in the partial pressure of carbon dioxide. In contrast, during the day, photosynthesizing plants, algae and bacteria consume carbon dioxide. As a result of these processes, the partial pressure of carbon dioxide in an intertidal pool can vary more than 1000-fold. The partial pressure of carbon dioxide also affects the pH of water, because as CO_2 dissolves in water it forms carbonic acid (H_2CO_3), then bicarbonate (HCO_3^-) and a proton (H^+). Seawater is well buffered, but despite this high buffering capacity, the pH of an intertidal pool can vary between a pH of 6.9 and 10.3 across the tidal cycle because of the large changes in the partial pressure of CO_2 resulting from the combination of photosynthesis (removing CO_2) and respiration (adding CO_2). Changes in pH can cause damage to skin and to the surface of the gills, and are an important sublethal stressor for fish. As with other stressors, intertidal fish are typically fairly resistant to the effects of changes in pH and can tolerate a wide range of pH conditions.

Glossary

Basal media A solution of buffering agents and of nutrients, which include a hexose, bulk ions, trace elements, amino acids, and vitamins.

Cell line Begins with the successful passaging of a primary culture.

CO_2 incubator A chamber that maintains temperatures a few degrees above ambient to approximately 40 °C and allows the injection of one or more gases, usually CO_2.

Cryopreservation Storing cells, usually in 10% dimethyl sulfoxide, at temperatures below −80 °C.

Culture vessels Commonly plastic flasks and also glass or plastic petri dishes.

Ecotoxicology An interdisciplinary science dealing with toxicants in the environment.

Epithelial-like cell line Majority of the cells attach and spread on the growth surface to have shapes like irregular patio blocks.

Fibroblast-like cell line Majority of the cells attach and spread on the growth surface to have long bipolar shapes.

Finite cell line Cells can undergo a limited number of population doublings.

Heat inactivation of serum Incubation at 56 °C for 30 min.

Immortal cell line Cells can be propagated indefinitely and are as same as a continuous cell line.

Laminar flow hood A cabinet in which sterile air is created by passing the air through a high-efficiency particle air filter in smooth or laminar flow and blown across a work area to create a sterile environment in which cultures can be manipulated.

Line Same as cell line.

Macrophage-like cell line	Majority of the cells express some macrophage properties, such as being highly phagocytic and having major histocompatibility class II proteins on the cell surface; often, proliferate loosely attached to the growth surface.
Passaging	Transfer of cells from one culture vessel to another. This is synonymous with subculturing, subcultivating, or splitting.
Primary cultures	A culture initiated directly from the cells, tissues, or organs of an animal.
Proliferation	An increase in cell number through cell division.
Senescence	Loss by cell lines of the ability to be propagated.
Serum	The fluid fraction after blood has been allowed to coagulate and trap blood cells with clotting factors into a solid clot.
Spheroid	An aggregate of cells in suspension within a culture.
Spontaneous immortalization	Cells acquire the ability to be grown indefinitely through only the routine maintenance of the cells in culture.
Trypsin	A protease from the pancreas that is used to passage cells.
Xenobiotic metabolism	Changes to foreign compounds brought about by cells or organisms.

Introduction

Cell lines are cultures of animal cells that can be propagated repeatedly and sometimes indefinitely. They arise from primary cell cultures. Primary cultures are initiated directly from the cells, tissues, or organs of animals and are typically used in experiments within a few days. By convention, the passaging or subcultivation of a primary culture begins a cell line. However, not all primary cultures yield cell lines. Instead, the cells of some subcultivated cultures die off slowly. Why the cells of other cultures keep on growing and allow these cultures to be continuously subcultivated is a complex and incompletely understood subject. The subject is intensively studied with mammalian cells because of the relevance of this to the mechanisms of cellular senescence and the origins of cancer cells. In the case of mammalian cell lines, some are finite. They can only be subcultivated a limited number of times before they senesce. Yet other mammalian cell lines are continuous or immortal and can be grown indefinitely. Continuing with the case of mammals, some primary cultures or finite cell lines can be experimentally immortalized to become continuous cell lines.

By contrast, with fish, little is known about cellular senescence and immortalization. Fortunately and surprisingly, many fish cell cultures have been subcultivated indefinitely. These cell lines are said to have become spontaneously immortalized. This is how nearly all fish cell lines have arisen. Most of these have been derived from bony fish, but they are called simply fish or piscine cell lines. The development of fish cell lines is described elsewhere (see the 'Further reading' section). Here, the sources and types of fish cell lines are noted and what is needed to maintain these cell lines is described, ending with a brief overview of how the cell lines are being used.

Sources

Like mammalian lines, fish cell lines can be stored frozen, aiding their distribution to researchers around the world. How piscine cell lines are cryopreserved is discussed later in the 'Cryopreservation' section. A recent list of repositories with fish cell lines has been presented (see the 'Further reading' section). Relative to the demand for human and rodent cell lines, the request for piscine cell lines is limited and so the number of fish lines in these cell banks is small. Despite the restricted choice, repositories are the best cell line sources. They assure quality and reliable delivery, but of course at a price.

Cell lines have been developed from most but not all tissues and organs of bony fish, with only a few from tumors, usually liver tumors. Most piscine cell lines are yet to be analyzed for differentiated properties and are described simply as being either epithelial-like or fibroblast-like. Exceptions are some lymphocyte and macrophage cell lines. **Figure 1** illustrates the morphologies in cultures of salmonid epithelial-, fibroblast-, and macrophage-like cell lines. Other properties commonly examined are the optimal growth conditions and the karyotype. Although diploid fish

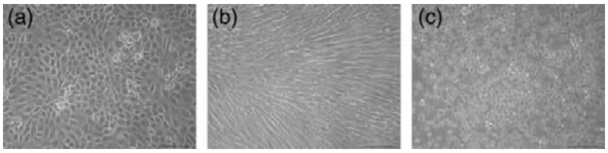

Figure 1 Phase-contrast microscopy appearance of cultures of an epithelial-like (a), a fibroblast-like (b), and a macrophage-like (c) cell line. The lines are RTgutGC from the epithelial layer of the rainbow trout intestine (a), AS20imf from the subepithelial layer of the Atlantic salmon intestine (b), and RTS11 from the rainbow trout spleen (c). Scale = 100 μm.

cell lines do exist, most cultures are heteroploid: they contain cells with chromosome numbers that are not an exact multiple of the haploid number.

Approximately 10 times as many fish cell lines have been described in the literature as have been placed in repositories. Lists of these have been prepared at several points over the last 30 years. Whereas ~29 000 species of bony fish in over 500 families have been classified, cell lines have been prepared from only about 75 species in 35 families. In the past, methods of confirming that a cell line was indeed from the stated starting species were problematic, but now species confirmation can be done reliably by DNA barcoding. This has revealed at least one surprise: epithelioma papulosum cyprini (EPC), which was thought to be a carp (*Cyprinus carpio*) cell line, is fathead minnow (*Pimephales promelas*). Over 10 different cell lines have been developed from each of several species, including catfish (*Ictalurus punctatus*), rainbow trout (*Oncorhynchus mykiss*), and zebrafish (*Danio rerio*). The total number of fish cell lines in the literature is now reaching close to 200, but many of these have likely been lost. Yet others are still available from the community of scientists developing and using piscine cell lines.

Whether from a repository or a colleague, the lines can be obtained as either a vial of frozen cells or as a flask of living cells. Sending flasks of cells is often easier because vials need to be embedded in dry ice, which imposes shipping restrictions and increases the shipping cost. Sending flasks of cell lines from coldwater fish in the summer might require placing the flask on an ice pack, but this poses no shipping problems. Getting living cultures is also easier. The cultures can often be subcultivated shortly after being received, and the problem of thawing the cells, the success of which can be variable, is avoided.

Equipment

At least three pieces of equipment are required to routinely maintain piscine cell lines. An inverted phase microscope is needed in order to visually inspect cultures. For passaging, a sterile environment is needed in order to open culture vessels and to remove or add cells without contaminating cultures with microbes. This is achieved in the working area of a laminar flow hood, which can be either vertical or horizontal, with the latter being less expensive. A vertical hood provides a current of sterile air between the worker and working area, protecting the worker from being exposed to any human pathogen that might inadvertently be associated with the cells. As there is no record of fish cell cultures containing human pathogens, a horizontal hood is often used. The third piece of equipment is a low-speed centrifuge to collect cells either for routine subcultivation or to set up experimental cultures. As discussed below, an incubator may or may not be required.

Culture Vessels

A vast array of plastic tissue culture ware has been developed for mammalian cells and nearly all these items work well with fish cell lines. Some of these items, such as flasks and petri dishes, are used for routinely growing cells, whereas others are used to monitor a particular endpoint. For the routine growth of piscine cell lines, nonvented flasks are favored because the loss of medium through evaporation is less. For RTS11, the most consistent growth is achieved with 12.5 cm^2 flasks, whereas for most other salmonid cell lines, 75 cm^2 flasks are convenient. In these, the cells grow to completely cover the flask surface and from a single flask, several multiwell plates can be set up for experimental purposes. With flasks >75 cm^2, RTL-W1 and RTgill-W1, and rainbow trout cell lines, are slow to cover the growth surface and often leave unfilled patches in the center.

Most plastic vessels are treated to promote animal cell attachment and proliferation, but some have hydrophobic surfaces to keep the cells in suspension. All these work for fish cell lines. In vessels with hydrophobic surfaces, suspended epithelial- and fibroblast-like cell lines aggregate over a few hours to form spheroids (**Figure 2**). Fish cells also attach to glass petri dishes. However, salmonid cell lines have been found to spread poorly in Lab Tek Chamber Slides (Nunc) with a glass surface, but do spread well when these slides have a plastic Permanox surface.

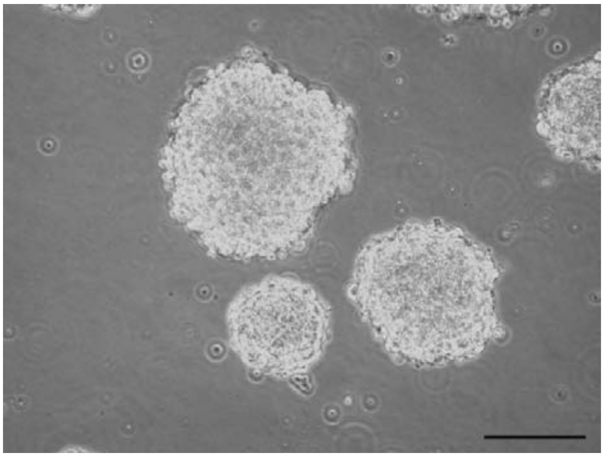

Figure 2 Phase-contrast microscopy appearance of spheroids formed in Nunc low-bind tissue culture dishes (coating of phospholipid polymer, 2-methacryloxyloxyethyl phosphorylchloline). The spheroids were initiated by adding 2×10^6 cells of the rainbow trout spleen stromal cell line (RTS34st) into 60 mm low-bind dishes. The medium was L-15 with 10% FBS, and after 24 h at room temperature, the culture was photographed. Scale = 100 μm.

Growth Media

The complete growth medium for the routine propagation of piscine cell lines has two essential parts, a basal medium and a supplement, with antibiotics being optional.

The basal medium constitutes an aqueous solution of buffering agents and of nutrients, which include a hexose, bulk ions, trace elements, amino acids, and vitamins. Basal media can be purchased, already made sterile in tissue-culture-grade water, or with all the constituents packaged as powders that need only be mixed with water. Some basal media are sold without glutamine because of its instability, and these are completed just before use by adding aliquots of a sterile concentrated glutamine solution (200 mM). Many different basal media are available commercially, and all were originally developed and optimized for mammalian cells. Fortunately, cells from other vertebrates, including both freshwater and marine fish, do well in them.

The choice of basal media for fish cells usually revolves around the availability of a CO_2 incubator, which is necessary to support the most common type of buffering system in basal media, sodium bicarbonate ($NaHCO_3$). For $NaHCO_3$ to act as buffer, a CO_2-rich atmosphere, usually 5% CO_2 and 95% air, is required and is provided for by a CO_2 incubator. Eagle's minimum essential medium (MEM) in Earle's salts is a basal medium that requires a CO_2 atmosphere and has been used frequently in the past to successfully grow a variety of fish cell lines. However, the use of CO_2 incubators for temperatures below room temperature is problematic for several reasons. As purchased, a CO_2 incubator can only raise the temperature, so a means of cooling has to be found for lower temperatures. The solubility of CO_2 increases at low temperatures, causing media to become acidic.

Two groups of basal media maintain their buffering capacity under normal atmospheric conditions (~0.03% CO_2) and are used to grow piscine cell lines. One group was developed for CO_2 incubators with slight modification. For example, MEM is made up in Hank's salts, which maintains the pH under atmospheric conditions. Another modification is the addition of organic buffers, such as HEPES. Many commercial basal media include either 15 or 25 mM HEPES plus the original concentration of sodium bicarbonate. Although buffering is usually optimal in a 5% CO_2 atmosphere, fish cells grow under atmospheric conditions. Another basal media group was formulated specifically for use in free gas exchange with air. The oldest is Leibovitz's L-15, which maintains physiological pH through a combination of salts, high basic amino acid concentrations, and galactose in place of glucose. A more recent addition is CO_2-independent medium (Gibco or Invitrogen). Unlike L-15, it contains sodium bicarbonate. Most fish cell lines are grown in L-15, but a few fish cell lines maintained in CO_2-independent medium grew well. These basal media are used without a CO_2 incubator.

The most common supplement is serum. Sterile sera from a few farm animals and sometimes fish sera are available commercially. Serum contains hundreds of proteins and is incompletely characterized, so it is described as an undefined supplement. No defined media have been reported yet that consistently support the proliferation of a piscine cell line through many passages.

Serum has to be added to basal media to improve fish-cell proliferation. For example, Atlantic salmon (*Salmo salar*) cell numbers slowly decline in L-15 over days to weeks (**Figure 3**). Yet, when L-15 is supplemented with 10% fetal bovine serum (FBS), cell number increases approximately eightfold over 2 weeks (**Figure 3**). Indeed, FBS with or without heat inactivation is the most common serum used for routine fish-cell growth. The usual FBS concentration is 10%, but ranges from 5% to 30% depending on the cell line. Sera from calves and horses are less expensive and infrequently used because of slower growth. Surprisingly, fish sera are rarely used, perhaps because FBS is cheaper and fish sera were found to be sometimes cytotoxic to fish cells.

For the routine maintenance of cell lines, antibiotics are added to media. Usually, these are penicillin at 100 IU with streptomycin at $100\,\mathrm{ug\,ml^{-1}}$ (penicillin/streptomycin). An alternative is to use gentamycin at $50\,\mathrm{ug\,ml^{-1}}$. Less frequently, an antifungal agent, amphotericin (fungizone), is added at variable concentrations. The use of antibiotics is often discouraged because consistent antibiotic use can lead to the development of resistant microbes and hide poor aseptic techniques.

Growth Temperature

The temperature range over which fish cells divide in culture is referred to as the proliferation zone and is wide. They tolerate an even wider temperature range,

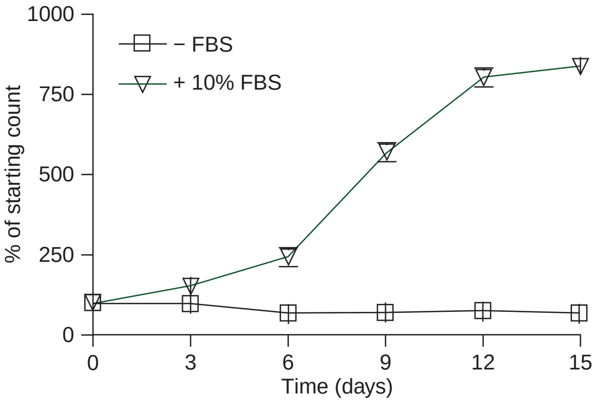

Figure 3 Change in cell number over time at room temperature for cultures of AS20imf in Leibovitz's L-15 either without a supplement (a) or with a supplement of 10% FBS (b). For each time point, cell number was counted with a Coulter counter in three replicate wells of a 12-well plate. The results are expressed as a percentage of the starting cell number, which was ~5.0×10^4 cells.

which has been defined as the endurance zone. The temperature chosen for a cell line depends on the purpose of the cultures, the species, and the availability of incubators. To maximize cell production, an optimal growth temperature should be selected. For cold-water fish, like salmon, this is in the 20–23 °C range; and for warm-water fish, like zebrafish, this is 26–30 °C. If the purpose is to just maintain the cultures for later use, lower temperatures allow the cells to slowly proliferate, reducing culture maintenance.

Nearly all fish cell lines grow at room temperature, which alleviates the need for an incubator or controlled rooms at other temperatures. The incubator type depends on the basal media. With L-15 or CO_2-independent media, a regular incubator can be used. However, if the temperatures are high and the incubator is not humidified, medium can rapidly evaporate from petri dish cultures, increasing the osmolarity and slowing cell growth. Therefore, in this situation and also for room temperature without an incubator, unvented flasks with the caps tightly closed are recommended. When buffering of the basal media is done only with sodium bicarbonate, a CO_2 incubator must be used.

Passaging

Passaging, which is also referred to as subculturing, subcultivating, or splitting, is the transfer of cells from one culture vessel in which the cells have been growing for days or weeks to two or more new culture vessels in which they will again be grown for days or weeks. This is routine maintenance and expands cell number. It is usually done in flasks.

Some fish white-blood cell lines, such as RTS11, grow in suspension or loosely attached to the growth surface and are the easiest to passage. A sterile cell scraper gently dislodges attached cells into the medium with the cells already in suspension. A pipette then removes aliquots of cell suspension into fresh medium.

In contrast to the lymphoid cell lines, most piscine cell lines are anchorage dependent and cells are removed from the flask growth surface before passage with or without enzymes as per commercially available step-by-step protocols. With fish cell lines, these steps are done at room temperature or lower. Trypsin is the most common enzymatic method, but the monolayer of cells must be rinsed with ethylenediaminetetraacetic acid to remove divalent cations prior to 0.01% trypsin being added. Trypsin usually causes the cells to round up and start detaching within 5 min, at which point medium with serum is added to stop the trypsin. Sometimes with older cultures, cells take longer to detach and sometimes cells clump on the addition of serum. Alternative methods include use of TryplE Select or Express (Invitrogen), trypsin-like enzymes produced by microbes. These are more convenient to use than trypsin and among their advantages is that serum need not be added to stop their actions. Nonenzymatic methods of splitting cultures act by chelating divalent cations. A commercial solution for this is cell dissociation solution nonenzymatic (Sigma), which is used to successfully passage several fish cell lines. Regardless of the dissociation method, a split ratio of one old confluent flask to two new flasks is common for slow-growing adherent cell lines from cold-water fish. With salmonid cell lines at room temperature, cultures can be commonly split one to two every 7–10 days. Higher split ratios can be used for more vigorously growing cell lines, such as EPC.

Cryopreservation

Cryopreservation of cell lines provides a supply of cells for some later date and involves the same methods used for mammalian cell lines. The usual cryoprotectants are dimethyl sulfoxide and glycerol at 5–10% (v/v) in the complete growth medium. Indefinite storage is done in Dewars of liquid N_2 at $-196\,^{\circ}\mathrm{C}$, but cells store for approximately a year in electrical freezers at $-80\,^{\circ}\mathrm{C}$. Cells are usually frozen slowly in several ways. One uses programmable coolers set at a cooling rate of often $-1\,^{\circ}\mathrm{C\,min^{-1}}$, but these are not usually available. Alternatively, vials in a polystyrene box, to ensure slow freezing, are placed in a -70 to $-90\,^{\circ}\mathrm{C}$ freezer for at least 2 h before being transferred to liquid N_2. A third strategy is to place vials in the atmosphere above the liquid N_2 in the Dewar and then after 2–24 h lower them into the liquid N_2. Rapid thawing and speedy cryoprotectant removal are key to getting high proportions (70–90%) of living cells, although even low viability (~10%) can lead to proliferating cultures of some fish cell lines.

Applications

The uses to which fish cell lines are being put keeps increasing. The first and most common application is to study viral diseases. The fastest growing area of use is in toxicology and ecotoxicology. Other research disciplines making use of fish cell lines include biomedicine, immunology, and animal physiology. Some applications defy easy classification, such as the use of a goldfish fibroblast cell line to explore the production of fish filets for long voyages in space.

Glossary

Gene knockdown Inhibition of gene expression by the presence of a specific blocking agent such as antisense morpholinos.

Malignant tumor Severe tumor type that is able to metastasize.

Metastasis Spread of a tumor from the primary place of origin to another part of the body.

Mutagenesis screen Forward genetic method to find novel genes of interest by introducing gene mutations into the genome of a model organism.

Oncogene Gene driving tumor formation when mutated or expressed at abnormal levels.

Promoter The upstream sequence of DNA which regulates the expression of the downstream coding sequence of the gene. The promoter may sometimes be as big as or bigger than the gene itself. A so-called 'minimal promoter' is the length of the promoter required to achieve expression of the gene, but without additional positive or negative elements.

Receptor tyrosine kinase Cell-surface receptor that activates intracellular signaling cascades in response to binding of specific extracellular ligand molecules.

Transcription factor DNA-binding protein that influences the expression of genes by binding to their promoter region.

Tumor modifier Genetic factor that influences the characteristics of a specific tumor type.

Tumor suppressor Gene that prevents tumor formation.

Introduction

Pigmentation and color patterning of body and fins serve multiple functions in fish, including camouflage, communication, mate choice, or species recognition. Fish pigmentation is highly polymorphic and often sex-specific, particularly during the spawning season. Furthermore, many fish species change their pigmentation during their life cycle. Prominent examples for colorful fishes are coral reef fishes, poeciliids from Middle and South America (guppy, *Poecilia reticulata*; platyfish, *Xiphophorus maculatus*; swordtail, *Xiphophorus hellerii*) or the cichlids of the East African Great Lakes. (**see also Vision**: Color vision and Color Communication in Reef Fish)

Coloration of teleost fishes is based on six different major types of pigment cells. Other fish lineages and tetrapods, in contrast, have a smaller repertoire of such chromatophores. Studying the genetic basis of fish coloration has a long tradition, particularly in East Asia, where color morphs of carp and goldfish have been cultured for more than 1500 years. In the beginning of the last century, poeciliids became popular among geneticists to study the inheritance of color patterns and also of pigment cell-derived tumors.

The present article gives an overview of the types of pigment cells found in fish, the genetic control of their development and differentiation, and the genes that underlie color polymorphisms between natural fish populations. Subsequently, we discuss the longstanding interest in fish as model systems for the study of pigment cell-derived types of skin cancer.

Pigment Cells in Fish

Development of Pigment Cells

There are two major types of pigmented cells in the vertebrate body. The black cells of the retinal pigment epithelium, the dark cell layer in the eye, are of neuroectodermal origin. In contrast, the pigment cells of the skin (chromatophores), which are the focus of the present article, derive from the neural crest.

The neural crest is a transient cell population during early embryonic development that arises in the dorsal ectoderm between the neuroectoderm and the prospective epidermis. From this layer, neural crest cells migrate along different routes throughout the embryo to their

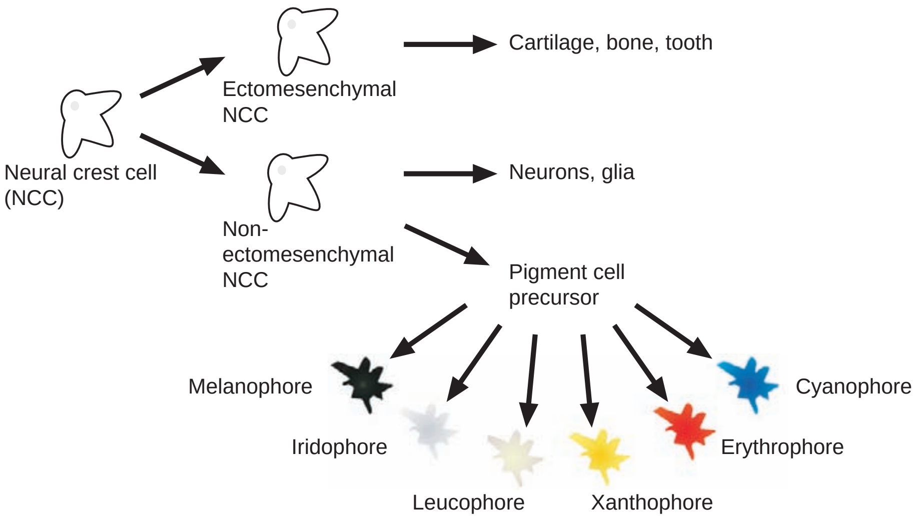

Figure 1 Specification of pigment cells from the neural crest.

final destinations. Neural crest cells give rise to around 50 different cell types including cartilage, neurons, and chromatophores. They are all initially multipotent, but they become gradually restricted to a particular cell fate during development. A first distinction can be made between ectomesenchymal and non-ectomesenchymal neural crest cells. The former give rise to cartilage, bone, and tooth tissues, while the latter develop into neurons, glia, and pigment cells. All pigment cell types develop from a common precursor cell (**Figure 1**).

Pigment Cell Types in Fish

In teleost fishes, six major pigment cell types can be recognized, each displaying characteristic pigments in specialized pigmentary organelles (**Figure 2**).

Melanophores synthesize the black to brown eumelanin in their melanosomes (**Figure 2**). In contrast to mammals and birds, teleosts do not synthesize the lighter pheomelanin.

The metallic-reflective iridophores store crystalline purines, particularly guanine, in so-called reflecting platelets (**Figure 2**(**a**)). The creamy-whitish leucophores also contain purines in their leucosomes (**Figure 2**(**b**)). Irido- and leucophores are closely related and generate structural colors by the reflection of light.

Yellow to red chromatophores are categorized according to their overall color either as xanthophores (yellow; **Figure 2**(**a**)) or as erythrophores (red). Both pigment cell types synthesize yellow to red pteridine pigments in their pigmentary organelles (pterinosomes), which are called xanthosomes or erythrosomes, respectively. In addition, xantho- and erythrophores may store yellow to red carotenoid pigments obtained from the food in carotenoid vesicles.

The blue cyanophores have so far only been found in two species of the family Callionymidae (dragonets), the mandarinfish *Synchiropus splendidus* and the picturesque dragonet *S. picturatus*. The pigmentary organelles of these cells, termed cyanosomes, contain a true blue pigment. In other fishes, blue is usually displayed as a structural color generated by iridophores.

The distribution of chromatophores, often combining stacked layers of different pigment cell types, generates

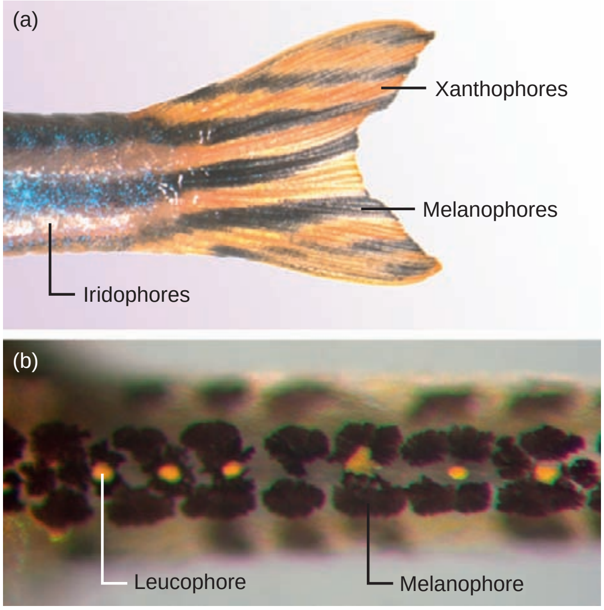

Figure 2 Teleost pigment cell types. (a) Tail and tailfin of an adult zebrafish showing the characteristic stripe pattern based on dark melanophores, yellow xanthophores and reflective iridophores. (b) Dorsal view on the trunk of a juvenile medaka. Cream-colored leucophores are surrounded by dark melanophores.

the endless diversity of stripes, spots, and patches of all types of colors in teleosts.

To the best of our knowledge, melanophores and iridophores are the only pigment cell types that have been described so far for agnathans (lamprey and hagfish), cartilaginous fishes (sharks and rays) and lobe-fin fishes (coelacanth and lungfish). (**see also The Skin**: Coloration and Chromatophores in Fishes).

Genetic Control of Pigment Cell Development

The identification of pigment genes, that is, genes that are involved in pigment cell development, pattern formation, pigment synthesis, or color change, has been spurred by the systematic analysis of pigment mutant collections of zebrafish (*Danio rerio*) and medaka (*Oryzias latipes*). An important resource for naturally occurring medaka pigmentation mutants is the Tomita collection. For zebrafish, a large collection of pigmentation mutants has been isolated from different large-scale mutagenesis screens. **Table 1** and **Figure 3** give some examples of pigmentation mutants for which the affected pigment gene has been found. In addition, some pigment genes have been functionally investigated by gene knockdown approaches. Several of the major pigment genes in fish will be introduced in the following.

Specification of Pigment Cells

The specification of the non-ectomesenchymal neural crest is regulated by the transcription factor Sox10. In the zebrafish *colorless* mutant, which is defective in the *sox10* gene, all types of pigment cells are severely reduced and defects in other non-ectomesenchymal derivatives are also observed.

All chromatophore types develop from a common precursor cell, but their relationships and the progression of fate restrictions to a particular type of chromatophore remain poorly understood. The analysis of zebrafish pigmentation mutants, however, has revealed that during development each type of chromatophore requires the expression of a characteristic transcription factor as well as of a transmembrane receptor from the family of receptor tyrosine kinases.

Melanophores

The zebrafish mutant *nacre* lacks almost all melanophores (**Figure 3**(**a**)). These fish are mutated in the *mitfa* gene. The Mitf transcription factor is the master regulator of melanophore development in vertebrates, and expression of *mitfa* is sufficient to specify precursor cells for the melanophore fate. Mitf binds to the promoters of melanin synthesis enzyme genes and upregulates their expression. The expression of *mitfa* itself is regulated by Sox10. Because of its specific activity, DNA constructs

Table 1 Examples of teleost pigment genes

Developmental/cellular function	*Gene*	*Teleost mutant*[a]	*Molecular function*
Neural crest specification	*sox10*	*colorless* (Dre)	Transcription factor
Melanophore specification	*mitfa*	*nacre* (Dre)	Transcription factor
Melanophore migration/survival	*kita*	*sparse* (Dre)	Receptor tyrosine kinase
Melanophore development	*tfap2a*	*lockjaw* (Dre)	Transcription factor
	hdac1	*colgate* (Dre)	Histone deacetylase
	trpm7	*touchtone* (Dre)	Cation channel

Pteridine synthesis regulation	*mycbp2*	*esrom* (Dre)	?

[a] Names of mutant lines from zebrafish (Dre) or medaka (Ola).
Some genes have been studied by gene knockdown (KD).

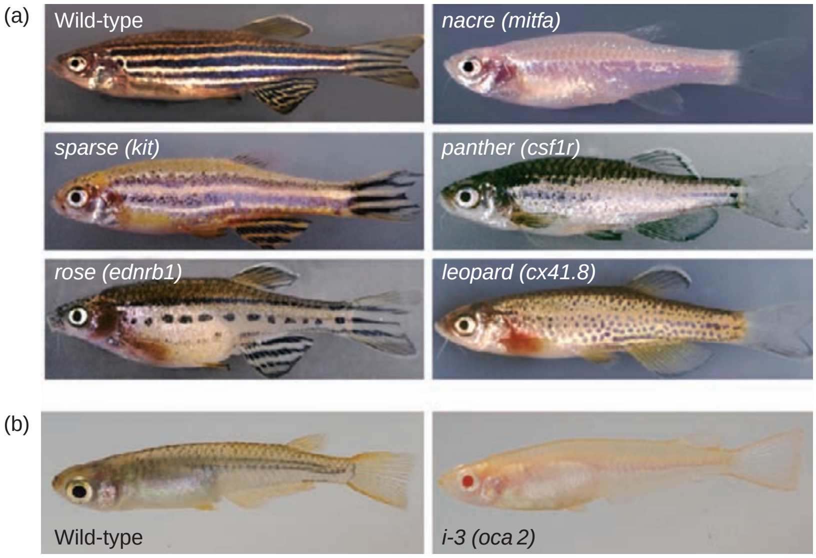

Figure 3 Examples of teleost pigmentation mutants. (a) Zebrafish mutants. Name and affected gene (in brackets) are given. (b) Wild-type medaka compared to the albino mutant *i-3*. (a) Adapted from figure 5 in Parichy DM (2006) Evolution of danio pigment pattern development. *Heredity* 92: 200–210.

containing the *mitfa* promoter can be used to artificially drive the expression of other genes into melanophores of transgenic fish. Such *mitfa* promoter constructs are essential tools for pigment cell and skin cancer research in fish (see below).

In teleosts, a second *mitf* gene, *mitfb*, regulates the expression of melanin synthesis enzymes in retinal pigment epithelium cells. The two *mitf* duplicates were generated in a teleost-specific whole genome duplication (**see also Cellular, Molecular, Genomics, and Biomedical Approaches**: Evolution of Fish Genomes). Many pigment genes are present in two copies in teleosts due to this event (recognizable by the suffix ‘a’ or ‘b’ after the gene name).

The receptor tyrosine kinase Kita is required for the migration and survival of melanophores. The *sparse* mutant lacks Kita function and is characterized by loss of embryonic as well as early stripe melanophores. Late stripe melanophores, in contrast, are present in *sparse* mutants (**Figure 3**(**a**)). The Kita receptor is activated and sends intracellular signals upon binding to Kit ligand a (Kitla). Knockdown of *kitla* in zebrafish decreases and *kitla* overexpression increases the number of melanophores.

Xanthophores

The specification of xanthophores in zebrafish requires the function of the Pax3 transcription factor. Pax3 is known to be important for melanocyte specification in mammals. Knockdown of *pax3a* genes in zebrafish, however, leads to a decrease of xanthophores, while melanophores increase in number. Pax3 presumably regulates the expression of genes required for xanthophore differentiation like the pteridine synthesis enzymes.

Very similar to the role of Kita for melanophores, the related receptor tyrosine kinase Csf1ra is required for xanthophore migration and survival. The corresponding *panther* mutant is devoid of most xanthophores and this absence of xanthophores seems to be responsible for the loss of the adult melanophore stripe pattern (**Figure 3**(**a**)).

Iridophores and Leucophores

The presence of the Foxd3 transcription factor is essential for the differentiation of iridophores. Its function appears to be the downregulation of *mitfa* expression in those precursor cells that will give rise to iridophores.

Iridophores also need a specific receptor tyrosine kinase for their development. The *shady* mutant, which shows reduced numbers of iridophores, was shown to be defective in the *leucocyte tyrosine kinase* (*ltk*) gene.

Although there are leucophore mutants in medaka (e.g., *leucophore free*), so far no genes has been identified that is involved in leucophore development.

Color Pattern Formation

Studies on color pattern formation have been focused mostly on the adult stripe pattern in zebrafish (**Figure 1**(**a**)). Mathematical models predict a reaction–diffusion mechanism generating this pattern and developmental studies have shown that interactions among melanophores and xanthophores are essential for stripe formation.

In the *leopard* mutant (**Figure 3**(**a**)), the adult stripe pattern is disrupted into a series of spots. It is mutated in the gap junction gene *connexin 41.8 (cx41.8)*. Gap junctions mediate tight cell–cell contacts, which is in line with the cell–cell interaction theory of stripe pattern formation.

Several genes are involved in the development of more than one type of pigment cell. One example is the *ednrb1a* gene, which is expressed in melano-, irido-, and xanthophores. Loss of this gene leads to defects in stripe patterning in the zebrafish *rose* mutant (**Figure 3**(**a**)). The loss of the growth hormone somatolactin in the medaka mutant *color interfere* results in an increase in leucophores and a simultaneous decrease in xanthophores. Many more genes involved in chromatophore development have been identified (some further examples are given in **Table 1**), but their discussion is beyond the scope of this article.

Pigment Synthesis Genes

Many teleost pigmentation mutants are characterized by lighter pigmentation (hypopigmentation) of chromatophores because of defects in pigment synthesis. Some of the responsible genes have been identified.

Melanin Synthesis

In melanophores and the retinal pigment epithelium, black eumelanin is synthesized from tyrosine by enzymes of the tyrosinase family: tyrosinase (Tyr), dopachrome tautomerase (Dct), and tyrosinase-related protein 1 (Tyrp1) (**Figure 4** (**a**)). Loss of eumelanin formation leads to different types of albinism. Mutant lines of the *i* (medaka) and *sandy* (zebrafish) type are complete albinos devoid of melanin pigments. Both mutants have a defective *tyra* gene. Knockdown of *tyrp1* genes in the zebrafish leads to a brownish type of albinism.

Several transporter proteins that reside in the melanosome membrane (**Figure 4**(**a**)) also have an influence on melanin synthesis, although their exact roles for melanin synthesis remain unclear. The albinistic medaka mutants *i-3* (**Figure 3**(**b**)) and *b* have defects in the *oca2* and *slc45a2* (also known as *aim1*) gene, respectively. The zebrafish *golden* mutant possesses hypopigmented melanophores. It was found to be affected in the *slc24a5* transporter gene.

Pteridine Synthesis

The synthesis of yellow to red pteridine pigments is highly complex and less well understood than melanin synthesis. The pteridine synthesis pathway has different branches, one of them leading to the formation of sepiapterin as a precursor for different types of pteridine pigments. Another branch leads to the formation of tetrahydrobiopterin (**Figure 4**(**b**)). Tetrahydrobiopterin is an important cofactor of the tyrosinase enzyme in melanophores, which directly links melanin and pteridine synthesis.

Although several mutants with altered pteridine pigments have been found in zebrafish, only one of them has been cloned so far. A mutation in the *mycbp2* gene in the

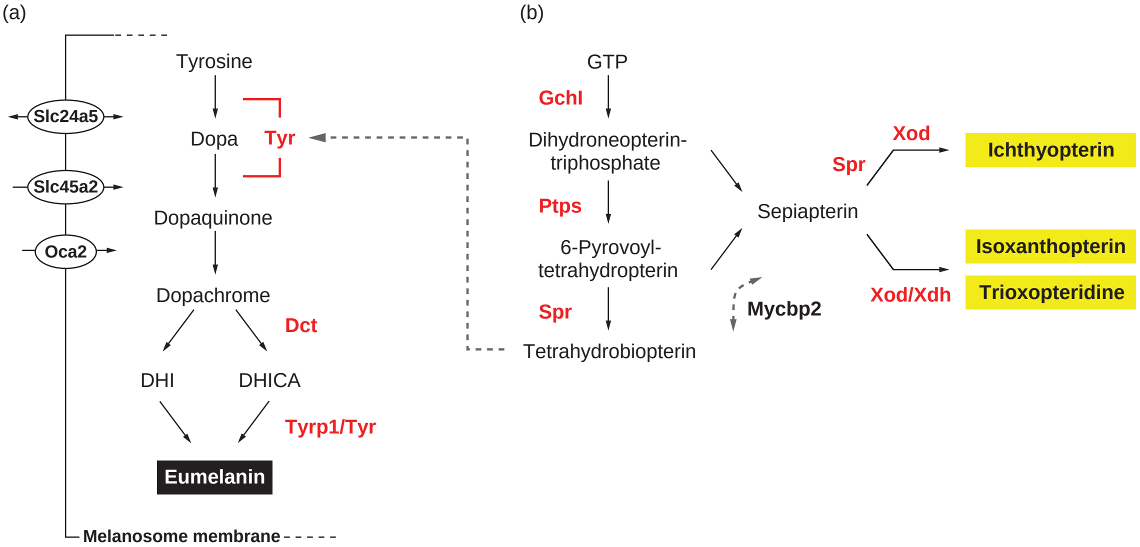

Figure 4 Pigment synthesis pathways. (a) Black eumelanin is synthesized from tyrosine by enzymes of the tyrosinase family. Tyr, tyrosinase; Dct, dopachrome tautomerase; Tyrp1, tyrosinase-related protein. Three melanosomal transporters (Slc24a5, Slc45a2, and Oca2) also play essential roles for melanin synthesis. (b) The pteridine synthesis pathway has two major branches: *de novo* synthesis of tetrahydrobiopterin (top to bottom) and formation of pteridine pigments via sepiapterin in xanthosomes (left to right). The switch between pathways is regulated by Mycbp2. In melanophores, Tetrahydrobiopterin is a cofactor of Tyr. GchI, GTP cyclohydrolase I; Ptps, 6-pyruvoyl tetrahydropterin synthase; Spr, sepiapterin reductase; Xod/Xdh, xanthine oxidase/dehydrogenase. Note that some intermediate pathway steps are not shown.

esrom mutant results in the reduction of yellow pigments. Mycbp2 may regulate the switching between different branches of pteridine synthesis (**Figure 4**(**b**)).

Color Change

Teleosts are famous for their ability to change colors (**see also Sensory Systems, Perception, and Learning**: Communication Behavior: Visual Signals). Morphological color changes are based on slow changes of pigment amounts or the distribution of chromatophores. Physiological color changes, in contrast, are accomplished by rapid movements of pigmentary organelles within chromatophores. In response to the endocrine and nervous systems, pigmentary organelles are moved along microtubules to the pigment cell center (lightening) or the periphery (darkening) (**see also The Skin**: Coloration and Chromatophores in Fishes).

A large body of literature exists on the regulatory role of hormones such as the melanophore-stimulating hormone (MSH) and the melanin-concentrating hormone (MCH) for physiological color change. Knockdown of the melanocortin-1-receptor (Mc1r), the receptor of MSH, impairs the dispersal of melanosomes. Melanosome transport mutants have been isolated in zebrafish. One of them has a defect in the *melanophilin a* (*mlpha*) gene, which encodes a structural protein coordinating the movement of melanosomes along microtubules.

Pigment Polymorphisms in the Wild

Geneticists, ecologists, and evolutionary biologists have extensively studied color differences among fish populations and species in the wild. For example, classic genetic studies have identified numerous pigmentation loci responsible for color differences among guppy and platyfish populations, many of them residing on the sex chromosomes. There are, however, only few studies in which the particular gene underlying a naturally occurring color polymorphism in fish has been identified.

Blind Cavefish

The Mexican tetra (*Astyanax mexicanus*) is a dramatic example for naturally occurring pigmentation divergence. While surface populations have a silvery-grayish appearance, blind cave populations independently lost the ability for proper melanin synthesis. It was shown that some of these albino forms of *A. mexicanus* are caused by loss-of-function mutation in the *oca2* gene. Brownish cave populations, in contrast, show changes in the melanocortin 1 receptor (Mc1r) compared to the surface populations. Modulation of Mc1r function is well known for being responsible for pigmentation polymorphisms and melanism in mammals, birds, and reptiles (**see also Bony Fishes**: Blind Cavefish).

Danio Species

Parichy and colleagues used an elegant method to pinpoint the developmental pathways responsible for stripe pattern differences between zebrafish and other species of the genus *Danio*. Several *Danio* species were crossed with pigmentation mutants of the zebrafish. These studies showed that stripe pattern differences between zebrafish and the stripe-less pearl danio (*D. albolineatus*) are due to modulations of the aforementioned Csf1r and Kit receptor tyrosine kinase signaling pathways.

Stickleback

The three-spined stickleback (*Gasterosteus aculeatus*) is well known for its pigmentary diversity around the globe. A recent study determined the gene responsible for differences in melanophore distribution between freshwater populations with light gills and bellies and ancestral marine populations with dark gills and bellies. These differences in melanophore patterning were traced back to differences in the expression of the *kit ligand a* (*kitla*) gene causing changes in melanophore distribution.

Pigment Cell Tumors

Under abnormal conditions, the broad spectrum of pigment cell types in fish can give rise to different types of skin tumors. Teleosts are therefore suitable models for the study of skin cancers, such as malignant melanoma, which is one of the most aggressive cancers with high rates of metastasis formation in humans. Naturally occurring spontaneous tumor growth from pigment cells in fish has been studied since the 1920s. Scientific reports on abnormalities in the skin of fish include erythrophoroma, melanoma, and iridophoroma, but only the first two types have been studied in more detail.

Goldfish Erythrophoroma

Large malformations in the skin of the goldfish (*Carassius auratus*) that are caused by uncontrolled growth of red pigment cells have been described. Further studies identified these lesions as erythrophoroma, that is, tumors arising from erythrophores. In subsequent studies, erythrophoroma cells were cultured and the erythrophoroma cell lines have since then been used for investigations of general pigment cell and tumor properties. However, the genetic alterations that may have caused the erythrophoroma formation in goldfish remain elusive.

Xiphophorus Melanoma

An extensively studied example of fish skin tumors is the appearance of black tumor lesions (melanoma) in hybrid species of the genus *Xiphophorus*. By crossing, for example, platyfish (*X. maculatus*) and swordtail (*X. hellerii*), hybrids can be generated that have spots with high numbers of melanophores (hyperpigmentation) and also invasive melanoma in the following generations.

The spontaneous tumor formation in *Xiphophorus* hybrids can be explained by the interplay of a tumor locus (*Tu*) that is under the control of a repressor locus (regulator locus *R*). Different chromosomal locations of *Tu* and *R* enable the stepwise separation of these two loci by repeated crosses to swordtail.

As shown in the crossing scheme in **Figure 5**, the platyfish genome contains, as well as the *Tu* locus, also the *R* locus, which represses the development of melanoma. After crossing a platyfish to a swordtail, which possesses neither *Tu* nor *R*, hybrids are born which have one *Tu*- and one *R*-bearing chromosome. This first hybrid generation is characterized by hyperpigmentation. A second crossing of these hybrids to swordtail results in four different genotypes. Half of the individuals from this generation will not show a pigmentary phenotype, because their genome is free of the *Tu* locus. One-quarter of fish will be strongly hyperpigmented due to the presence of one *Tu* and one *R* locus allele. One-quarter of individuals will develop malignant melanoma due to the presence of the *Tu* locus and the absence of an *R* locus in their genome.

Positional cloning of the *Tu* locus identified the oncogene *xmrk* (*Xiphophorus* melanoma receptor kinase) as the genetic factor driving the transformation of a melanophore into a malignant melanoma cell. Xmrk is an epidermal growth factor receptor (Egfr) that belongs to the group of receptor tyrosine kinases. The *xmrk* gene originated by a local gene duplication of the *egfrb* gene, which is located like *xmrk* on the platyfish sex chromosome.

The *xmrk* gene is highly expressed in melanoma tissues. Two mutations keep the Xmrk receptor in a constantly active form, thereby allowing ligand-independent signaling. Xmrk turns on different signaling pathways such as the phosphatidylinositol 3-kinase, the Ras–Raf–Mapk, or the Fyn/focal adhesion kinase pathways. These downstream signaling cascades increase cell proliferation, cell survival, and cell motility of the transformed pigment cell. Such changes in cell characteristics as well as activation of the same signaling pathways are also observed in human melanoma. For example, aberrant signaling through the Raf–Ras–Mapk pathway is well described for human melanomas, and mutated receptor tyrosine kinases are known to be involved in human cancer formation and progression.

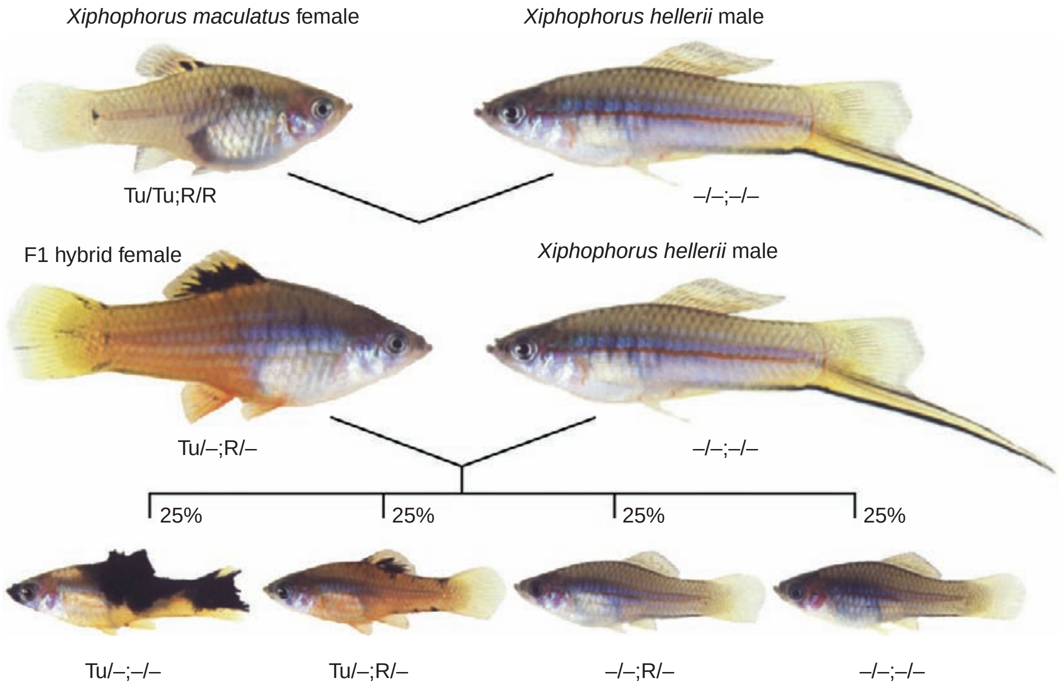

Figure 5 Crossing scheme of spontaneous melanoma formation in *Xiphophorus* (Gordon–Kosswig–Anders cross). Mating of a *X. maculatus* female (carrying *Tu* and the repressor *R*) to a *X. hellerii* male (lacking *Tu* and *R*) gives rise to a hyperpigmented hybrid generation (heterozygous for *Tu* and *R*). Further crossing of these hybrids to a *X. hellerii* male results in (from right to left) 50% fish with normal pigmentation (lacking *Tu*), 25% hyperpigmented fish (one copy of *Tu* and *R*), and 25% fish that develop malignant melanoma (carrying *Tu* but lacking *R*). Reproduced from figure 1 in Meierjohann S and Schartl M (2006) From Mendelian to molecular genetics: The *Xiphophorus* melanoma model. *Trends in Genetics* 22: 654–661.

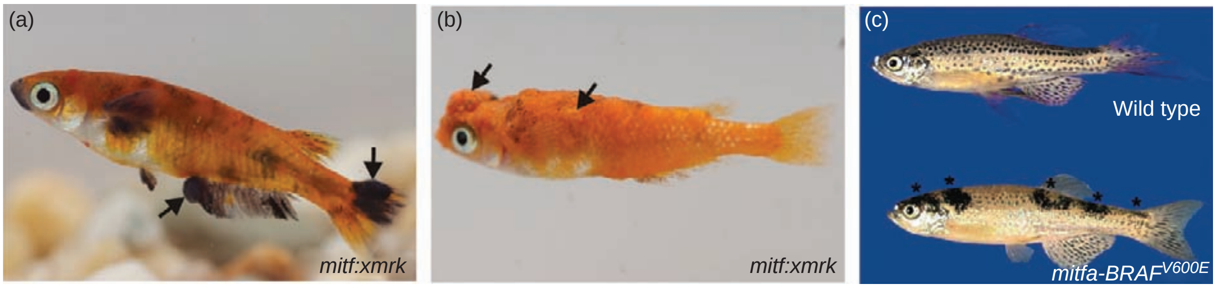

Figure 6 Different skin tumor phenotypes in transgenic medaka and zebrafish. Transgenic Medaka expressing *xmrk* in pigment cells under the control of the *mitfa* promoter develop (a) black melanoma and (b) red xantho-/erythrophoroma (arrows). (c) Zebrafish of the *leopard* strain expressing human *BRAF*^{V600E} in pigment cells (bottom) show growth of nevi (asterisks). Reproduced from figure 1B in Patton EE, Widlund HR, Kutok JL, *et al.* (2005) BRAF mutations are sufficient to promote nevi formation and cooperate with p53 in the genesis of melanoma. *Current Biology* 15: 249–254.

The *Xiphophorus* crossings indicate that besides the presence of *Tu*, the absence of the tumor suppressor *R* is necessary for tumor formation (**Figure 5**). In the platyfish, *R* counteracts *xmrk* and impedes the formation of tumors. The corresponding gene has not been identified yet, but based on genetic studies, one major candidate gene has been identified, *cyclin-dependent kinase inhibitor 2* (*cdkn2*), which maps to the chromosomal region of the *R* locus. Cdkn2 proteins act as cell-cycle and cell-proliferation regulators and have been intensively studied in human melanoma. *CDKN2* genes are often mutated in human melanomas. Conclusive evidence that *cdkn2* in *Xiphophorus* is indeed the *R* locus-encoded gene, however, is still elusive.

Transgenic Skin Tumor Models

Besides the appearance of natural spontaneous pigment cell tumors, several new approaches have been developed to study melanoma formation in fish. Recently, progress in molecular biology opened up the possibility to design genetic models of skin tumors in laboratory fish species such as zebrafish and medaka (**see also Cellular, Molecular, Genomics, and Biomedical Approaches**: Fish as Model Organisms for Medical Research). These skin tumor models show melanoma formation after chemical treatment, radiation, or the expression of an oncogene under a pigment cell-specific promoter.

One example for such a transgenic tumor model is the *mitf:xmrk* medaka, in which the *xmrk* gene from *Xiphophorus* is artificially expressed in medaka pigment cells under the control of the *mitfa* promoter. The transgenic fish develop, after a relatively short time, red xantho-/erythrophoroma and black melanoma (**Figure 6**). Both tumor cell types show specific characteristics of their own, such as different gene expression profiles, different tumor growth properties, and differences in invasiveness. Interestingly, appearance of the different tumor types depends on the genetic background of the fish, indicating the presence of different tumor modifiers genes.

Another example of newly established melanoma models is the *BRAF*^{V600E} zebrafish. Braf is a protein kinase of the Ras–Raf–Mapk pathway. In humans, mutations in this gene, for example, the common *BRAF*^{V600E} mutation, are associated with various cancers including malignant melanoma. In the transgenic zebrafish, the expression of the human *BRAF*^{V600E} gene under the control of the *mitfa* promoter drives the appearance of nevi (**Figure 6**(**c**)). Nevi, commonly called moles, are nonmalignant proliferations of melanophores. Further depletion of the tumor suppressor gene *p53* is necessary for the *BRAF*^{V600E} zebrafish to develop malignant melanoma. In a second zebrafish model, artificial expression of oncogenic human *RAS* in melanophores is sufficient to induce the formation of malignant melanoma.

Besides the transgenic models described here, other known melanoma oncogenes remain largely uninvestigated in fish. However, there are many promising candidate genes from human melanoma research including some of the pigment genes discussed in the previous sections (e.g., *mitf* and *kit*). Currently, fish models for other known oncogenes or other types of cancer are generated and make fish a valuable model system for cancer research.

Glossary

Heterogamety Production of different types of gametes with different sex chromosome content in one sex of a species. For example, in male heterogamety (XY males and XX females), males produce gametes with either an X or a Y chromosome, whereas females produce only gametes with X chromosome.
Neofunctionalization Acquisition of a novel function by a gene.
Paralogons Large, duplicated regions in a genome.
Polyploidization Increase of the chromosome set number (ploidy), for example, through the fusion of unreduced gametes (with somatic ploidy).
Rediploidization Karyotype rearrangement restoring a diploid karyotype (2*n*) from a tetraploid karyotype (4*n*).
Retrotransposon Transposable element transposing through retrotransposition, that is, reverse transcription of messenger RNA (mRNA) and integration of the complementary DNA copy into a new DNA target site. Retrotransposition leads to the duplication of the element.
Reverse transcriptase RNA-dependent DNA polymerase that catalyzes reverse transcription of mRNA into complementary DNA during retrotransposition.
Speciation Evolutionary process leading to the formation of a new species.
Subfunctionalization Complementary distribution of the functions of an ancestral single-copy gene between duplicates after duplication.
Transposable element DNA sequence able to integrate autonomously or nonautonomously into a genome.

In vertebrates, fish are subdivided into jawless fish (hagfish and lampreys), cartilaginous fish (sharks and rays), and bony fish (coelacanth, lungfish, and ray-finned fish including teleost). Fish, particularly teleosts, display a remarkable level of diversity affecting their reproduction, development, morphology, physiology, ecology, behavior, and many other facets of their biology. Many biological processes such as sex determination, which are well conserved in the mammalian lineage, are particularly variable in fish, with major differences even between populations from the same species. This important biodiversity is also reflected by the number of species: with over 25 000 species, fish represent the most diverse group of vertebrates (about 50% of extant vertebrate species). Particularly, ray-finned fish represent over 95% of all living fish species, with about 99% of them belonging to teleosts. Altogether, there is a mass of observations indicating that fish can evolve very rapidly, urging on the search of genes and regions affected by adaptive changes in their genomes.

Besides cytogenetical analyses of chromosome number and DNA content measurements, genome projects and other sequencing programs have been performed for several key species. The genome of the pufferfish (*Takifugu rubripes*; Fugu) was the second vertebrate genome to be sequenced after the human genome, followed by that of *Tetraodon nigroviridis*, another pufferfish. Both species have been chosen for the compactness of their genome. Genome sequences are also available for the threespine stickleback (*Gasterosteus aculeatus*), the medaka (*Oryzias latipes*), and the zebrafish (*Danio rerio*). The genome will be sequenced soon for other species including cichlids, salmonids, and catfish, and survey sequencing has been already performed for the elephant shark (*Callorhinchus milii*; cartilaginous fish). Comparative analyses have illuminated our understanding of structure and evolution of genomes in fish and other vertebrates including human.

Among others, comparison of tetrapod and fish genomes allowed the reconstruction of the karyotype of their last common ancestor that lived approximately 450 million years ago.

Genome Size and Chromosome Number in Fish

Even prior to the advent of genome sequencing, the level of diversity affecting fish at the genomic level was already demonstrated by the measurement of DNA content in haploid cells (the so-called haploid C-value in picograms, with 1 pg roughly corresponding to 1000 megabases of DNA; in tetraploids the C-value may represent two genomes within a same nucleus). Haploid DNA content in ray-finned fish varies from 0.35 pg in the pufferfish (*T. nigroviridis*) to 9.32 pg in the shortnose sturgeon (*Acipenser brevirostrum*; a polyploid species), with a range of variation several fold greater than most other major vertebrate lineages. Some families have particularly compact genomes, for instance, the Tetraodontidae including *T. nigroviridis* and *T. rubripes*, or large genomes, for example, Acipenseridae (sturgeons), Salmonidae, and Polypetridae (bichirs). Outside of ray-finned fish, coelacanth, hagfish, and cartilaginous fish have large genomes (e.g., 16.41 pg in the Australian angel shark (*Squatina australis*)). However, the most impressive genome sizes are found in lungfish (132.83 pg in the marbled lungfish (*Protopterus aethiopicus*)).

Chromosome number, as assessed in normal somatic cells, is also variable, from 22 (in some mudminnows of the *Umbra* genus) to 250 (in the Russian sturgeon (*Acipenser gueldenstaedtii*)). As reported in amphibians and reptiles, but not in mammals and birds, early and recent episodes of polyploidization have been observed recurrently during ray-finned fish evolution. Examples include sturgeons, salmonids, catostomids (suckers), and cyprinids, as well as non-ray-finned fish (e.g., lampreys). However, over 50% of ray-finned fish species analyzed so far have either 48 or 50 chromosomes, reflecting probably their ancestral karyotype.

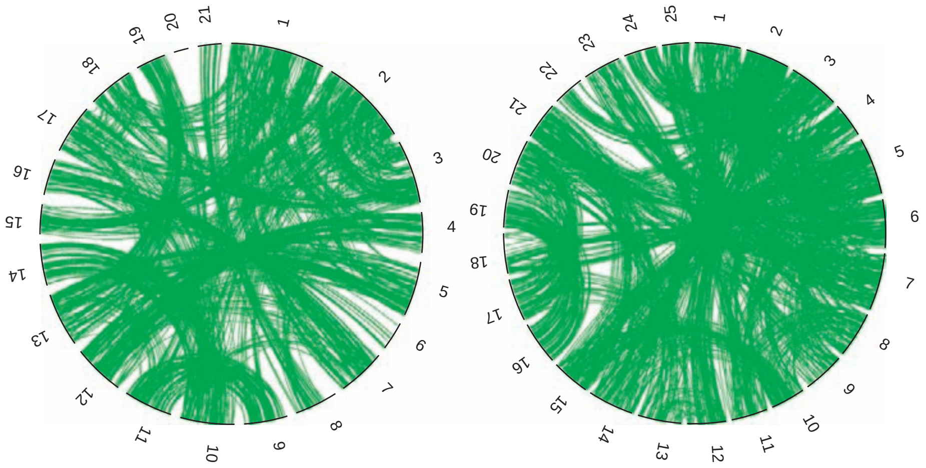
In many cases, higher DNA content results from polyploidization. However, 5–10-fold genome size differences are observed even between teleost species with the same chromosome number, suggesting variable degrees of genome compaction.

Ancestral Teleost-Specific Genome Duplication and Biodiversity

Many authors have reported the existence of genes present as single copies in tetrapods but duplicated in divergent teleost species. The classical example is provided by *hox* genes. This group of related genes, generally arranged in clusters, encodes transcription factors determining the positional specification of the anterior–posterior axis during early embryonic development in animals. The presence of four *hox* clusters in tetrapods compared to one cluster in invertebrates was one of the first hints suggesting that two rounds of genome duplications had taken place during early vertebrate evolution. Strikingly, teleost fish have even more *hox* clusters: at least seven clusters have been identified in zebrafish, pufferfishes, medaka, cichlids, and salmonids. This suggested the occurrence of an additional round of genome duplication during early evolution of the lineage, leading to teleosts after divergence from tetrapods. This teleost-specific genome duplication (TSGD) was confirmed through identification of thousands of protein-coding duplicated genes in teleost genomes that are single copy in tetrapods. Most of them have been formed within a same time window, about 320–350 million years ago. As expected from a whole genome duplication event, large syntenic duplicated regions (paralogons) have been identified in all teleost species studied so far (**Figure 1**). Altogether, convergent observations provide strong evidence for an ancestral genome duplication event having occurred after the divergence of bowfin, paddlefish, sturgeon, and bichir from the stem lineage leading to teleosts. This event was followed by rediploidization of the genome, since the great majority of teleost species has a diploid genome. After rediploidization, several thousands of pairs of gene duplicates generated by the TSGD have been conserved over several hundreds of million years in teleost genomes. Many of them are key developmental genes working as transcription factors or signaling molecules. Particular biological pathways (e.g., pigmentation) display a high rate of retention of TSGD duplicates.

According to Susumu Ohno and others, genome duplication has been proposed to generate a framework allowing genetic innovation and major evolutionary transitions. Hence, teleost fish represent an excellent model to understand the consequences of the massive duplication of genetic information on organismal complexity and biodiversity. Particularly, the availability of two divergent model species, the zebrafish (*D. rerio*) and the medaka (*O. latipes*), allows to establish not only the similarities but also the differences in evolutionary trajectories for a same pair of duplicates in two lineages separated by at least 150 million years of evolution.

Persistence of duplicated genes can be explained by different mutually nonexclusive mechanisms. Besides possible advantages of increased gene expression associated with the presence of a second functionally redundant copy, duplicated genes can experience functional divergence. This can be manifested by mutations changing the quantitative, spatial, or temporal transcriptional context or the coding potential of the copies. If one



Tetraodon nigroviridis

Danio rerio

Figure 1 Rose-window analysis of large duplicated regions (paralogons) in the genomes of the zebrafish *Danio rerio* and the pufferfish *Tetraodon nigroviridis*. Chromosomes are in black, individual duplicated genes are linked by green lines. The presence of large paralogons is diagnostic of an event of genome duplication.

duplicate acquires a novel, positively selected function different from the ancestral one, the process is called ‘neofunctionalization’. Alternatively, original functions performed by the ancestral gene might be distributed between both the duplicates through reciprocal mutations (subfunction partitioning/subfunctionalization). For example, from an ancestral single-copy gene expressed in testis and brain, after duplication one copy might be expressed only in brain (regulatory sequences for expression in testis have been lost) and the second copy only in testis (brain-specific regulatory sequences have been lost). Subfunctionalization can also occur through mutations in coding regions, for example, in different functional domains of a protein. Combinations of both models are of course possible: subfunctionalization of duplicated genes might correspond to a transition state to neofunctionalization. Subfunctionalization might allow innovation in one ancestral function without affecting the other (e.g., optimization of the function in brain without negative consequences on the function in testis). Many examples of TSGD duplicates having undergone subfunctionalization have been reported, including genes for the microphthalmia-associated transcription factor (MITF), the hormone precursor proopiomelanocortin, the Engrailed 2 homeoprotein and many others. Neofunctionalization has also been proposed to explain the maintenance of certain gene duplicates in fish, for example, through the acquisition of novel regulatory sequences or protein domains.

It has been proposed that the ancestral TSGD has provided the framework for the high level of biodiversity and speciation observed in teleosts. One possible mechanism is called ‘divergent resolution’ or ‘reciprocal gene loss’, a process in which each of the two populations loses a different copy from the same pair of duplicated genes during rediploidization. If divergent resolution occurs at multiple loci, this theory predicts genomic incompatibility associated with reduced fertility and/or viability of hybrids between the two populations (many genes will be completely absent or haplo-insufficient in hybrids), and therefore speciation. Accordingly, divergent resolution has been observed for some *hox* gene clusters in different teleost species and it has been estimated that as many as 1700 TSGD duplicate pairs (i.e., about 7% of original TSGD pairs) have lost different copies in *Tetraodon* and zebrafish. Alternatively, differential subfunctionalization of duplicate pairs in different populations would have similar effects as divergent resolution.

Taken together, there is compelling evidence that thousands of TSGD-derived genes have experienced lineage-specific loss or evolution (differential sub-/neofunctionalization), and that such a differential evolution has strongly contributed to biodiversity and, probably, speciation in teleost fish. Analysis of more recent events of tetraploidization in fish will allow determination of the initial steps of genome duplications. Of particular interest will be comparison of the process of rediploidization in two salmonid species, Atlantic salmon and rainbow trout, for which genome draft sequences should be available soon.

As observed in other organisms, more local events of gene duplication also contribute to organismal evolution and diversity in fish. For example, duplication and neofunctionalization of vertebrate vitellogenin genes might be associated with preadaptation of eggs to marine environment and might represent a key event in the evolution and success of teleosts to the marine environment.

Diversity of Transposable Elements

Transposable elements are sequences able to integrate into genomes. They are found in all genomes where they can induce various types of mutations. Through insertion they can disrupt genes and generate mutant phenotypes. In addition, many transposable elements have literally infested genomes and contribute very significantly to their size. For example, as much as 40–50% of the human genome is constituted by transposable elements. This is particularly true for retrotransposable elements, which generate new copies of themselves through messenger (mRNA) reverse transcription and complementary DNA (cDNA) integration, a mechanism of duplication called 'retrotransposition'. In contrast, most DNA transposons transpose through a cut-and-paste mechanism. Interspersed copies of the same transposable element integrated at different locations can recombine, generally by homologous recombination, and induce chromosomal rearrangements such as deletions, duplications, inversions, and translocations. Insertion of transposable elements in the vicinity of resident genes can modify their transcriptional context. Transposition itself can also produce different types of rearrangements at insertion sites. Parts of transposable elements inserted into introns can be recognized as exons by the host splicing machinery, thereby disrupting the open reading frame of a gene at the mRNA level (exonization). Taken together, the genomic effects of transposable elements are similar to those of any other form of genetic variability: some induced mutations can be deleterious to the host, but can also be beneficial when positively selected.

In addition, evidence has emerged that transposable elements serve as a genomic reservoir of regulatory and coding sequences, which can be recruited by resident genes during evolution. Many important genes in plants and animals have been formed directly from transposable elements (molecular domestication). Hence, transposable elements can be considered as major drivers of gene and genome evolution.

The presence of both DNA transposons and retrotransposable elements has been demonstrated in fish, but with a much lower global copy number than in mammals. Most of the 10 superfamilies of cut-and-paste DNA transposons recognized in living organisms have been identified, including Tc1/mariner, hAT, PIF/Harbinger, piggyBAC, and Merlin and P elements. Fish genomes also host Maverick/Polinton sequences, a group of self-synthesizing DNA transposons with long terminal-inverted repeats encoding a protein-primed DNA polymerase B and a retroviral-like integrase. Mavericks/Polintons encode a conserved set of proteins with homology to replication and packaging proteins of bacteriophages and eukaryotic double-stranded DNA viruses. Finally, fish genomes also contain two lineages of a particular superfamily of DNA transposons called 'Helitrons', which probably amplify through a rolling-circle mechanism and are able to capture other genomic sequences. Miniature inverted transposable elements (MITEs), nonautonomous sequences which do not encode any protein, are also found in fish. MITEs parasite the enzymatic machinery of coding autonomous elements to catalyze their own transposition.

All major types of reverse transcriptase-encoding retrotransposable elements have been identified in fish genomes. All groups of long terminal repeat (LTR) retrotransposons are represented, including Ty3/Gypsy, BEL-like, and Ty1/Copia retrotransposons. These elements are flanked by LTRs in direct orientation and encode among other a retroviral-like integrase. Endogenous vertebrate retroviruses, which are integrated remnants of past infections, are also found in fish genomes. Vertebrate retroviruses are structurally and phylogenetically related to Ty3/Gypsy, with an additional envelope gene necessary for infection. DIRS1-like tyrosine recombinase-encoding LTR retrotransposons, with more complex LTRs, are widespread in fish. Fish genomes contain retrotransposons without LTRs (called non-LTR retrotransposons of long interspersed nuclear elements (LINEs)). Some of these elements encode an apurinic–apyrimidinic endonuclease to cut their target integration site. Other fish non-LTR retrotransposons related to invertebrate elements have another type of endonuclease, possibly related to restriction enzymes. Finally, short interspersed nuclear elements (SINEs), which are noncoding retrotransposable elements using the non-LTR retrotransposition machinery of non-LTR retrotransposons, are present in fish genomes too.

Strikingly, fish genomes contain more types of transposable elements than mammalian genomes. Active Ty3/Gypsy, BEL-like, and Ty1/Copia, and DIRS1-like retrotransposons are absent in mammals. This is also the case for certain types of non-LTR retrotransposons and DNA transposons, for example, Helitrons. If we consider ancient phylogenetic families within a given type of element, the difference of transposon diversity between fish and mammals is even more impressive. For instance, within Ty3/Gypsy retrotransposons, at least nine ancient phylogenetic groups are present in fish and invertebrates. None of them is present as an active element in mammals. Taken together, from 26 ancient families of ancestral nonretroviral retrotransposable elements detected in at least one fish lineage and in invertebrates, only three are still present in human and mouse genomes, and most of them are not detected in chicken. Even the very compact genomes of pufferfishes with their low repeat content show a much higher diversity of endogenous retrotransposons than mammalian genomes. These observations suggest that a massive reduction of mobile DNA diversity has occurred during the evolution of the tetrapod lineage after its split from the ray-finned fish lineage.

There is no doubt that transposable elements contribute to genome and phenotype diversity in fish. Comparative analyses of sequenced fish genomes have demonstrated that different families can have very different copy numbers and levels of activity in different fish species. Some elements are very active in some species and have been completely eliminated in others. Even for widespread retrotransposons such as the Rex3 or Rex1 non-LTR retrotransposons, phylogenetic survey of different species revealed many independent bursts of retrotransposition potentially associated with speciation events. Many endogenous transposable elements are still active, as demonstrated by the identification of mutant phenotypes generated though gene disruption (e.g., the Tol2 DNA transposon in medaka or the TX1 retrotransposon in platyfish).

Rapid Evolutionary Turnover of Sex Chromosomes

Sex chromosomes are specialized chromosomes carrying genes that determine the sex of individuals (genetic sex determination). Males and females possess different sets of sex chromosomes. In mammals, males have an X and a Y chromosome (male heterogamety), while females have two X chromosomes. Birds have a genetic system with female heterogamety, with ZW females and ZZ males. Sex determination is controlled by the same XY system in the immense majority of mammals, and by the same ZW mechanism in most bird species. Both mammalian and bird sex-determination systems are ancient and have been formed at least 100 million years ago.

The situation is completely different in fish, where almost all possible forms of genetic sex determination have been observed (**see also Cellular, Molecular, Genomics, and Biomedical Approaches**: Molecular and Chromosomal Aspects of Sex Determination). Of course, not only simple systems with male or female heterogamety, but also more complicated systems with several or several pairs of sex chromosomes or without sex chromosomes are found, though with the involvement of several genomic loci (polyfactorial sex determination). Male or female heterogameties are frequently overridden by autosomal loci (autosomal influence) or by external parameters such as temperature, water pH, or social factors. In addition, different forms of hermaphroditism have been described in fish, as well as gynogenetic species reproducing as all-female clonal progenies. Importantly, plotting sex-determination mechanisms on a fish molecular phylogeny indicates a very frequent switch between sex-determination mechanisms in fish during evolution. Different systems of genetic sex determination can be found in a same fish genus and even in a same species (e.g., in the platyfish).

Frequent change of genetic sex-determination systems is associated with an astonishing turnover of sex chromosomes in fish. Comparative mapping experiments in different fish lineages have revealed that related species can have sex chromosomes from independent origins, even if they possess a same type of genetic sex determination. For example, comparative mapping of the sex-determining locus in different salmonid species with XY sex-determination mechanisms strongly suggests that they have different sex chromosomes.

In the best-studied model for sex determination, the medaka (*O. latipes*), the male-inducing sex-determining gene has been identified on the Y chromosome by two different research groups. This gene, alternatively called *DMY* and *dmrt1bY*, is the first master sex-determining gene to be identified in a nonmammalian vertebrate species. This master gene is rather recent (10 million years old) and has been formed after duplication and mutation of an autosomal gene called *Dmrt1*. When *dmrt1bY* is inactivated, XY genotypes are females. Transgenic expression of *dmrt1bY* induces testis differentiation and male development in XX genotypes. Hence, *dmrt1bY* is the bona fide master sex-determining gene of the medaka.

The Y-specific region is very small, and only contains *dmrt1bY* as a functional gene. There is no evidence of degeneration on the Y of neighbor genes also present on the X, as it is the case, for example, in mammals. Hence, medaka sex chromosomes might be of rather recent evolutionary origin. Accordingly, the age of *dmrt1bY* and of medaka Y chromosome has been estimated at only about 10 million years. The same master sex-determining gene is found in the related species *Oryzias curvinotus* but not in a more divergent *Oryzias* species, which has a different pair of sex chromosomes. This indicates that species from the same genus can have different sex chromosomes. Surprisingly, *O. luzonensis*, a sister species of *O. curvinotus* also with an XY system, has already lost *dmrt1bY* and possesses a new Y chromosome. Studies on other major models of genetic sex determination, such as the threespine stickleback (*G. aculeatus*), cichlids, and poeciliids, also support a very high turnover of master sex-determining genes and sex chromosomes in fish in association with the important level of diversity affecting sex determination.

Loci involved in sexual selection and hybrid sterility are found on various fish sex chromosomes. In the threespine stickleback (*G. aculeatus*), a newly evolved sex chromosome was recently shown to carry genes for male courtship display, that is, traits that contribute to behavioral isolation and therefore to speciation. Hence, sex chromosome turnover might play a role in reproductive isolation and speciation in fish.

Conclusion

Teleost fish genomes display several remarkable features suggesting a link between genome plasticity and phenotype diversity. Many duplicated genes have been formed through an ancient event of genome duplication. Divergent evolution of these duplicates has been observed in different fish lineages and might correspond to a major mechanism driving biodiversity and speciation in fish. Fish genomes contain many families of active transposable elements that can have very different activities in different fish lineages, thereby generating genomic and phenotypical diversity. In addition, sex chromosome turnover is very rapid in fish. Since sex chromosomes often carry genes involved in reproductive isolation, the rapid evolution of sex chromosomes might also significantly contribute to biodiversity and species formation. Finally, other features of fish genomes might favor diversity, such as a high rate of gene-linkage disrupting rearrangements as well as fast evolution of protein-coding and conserved noncoding, potentially regulatory sequences.

It is important to emphasize that most of these observations are based on key genome draft sequences from only five out of 25 000 fish species, with two of them being closely related (Fugu and *Tetraodon*). All of them are teleost species, making it difficult to assess the ancestral state within the ray-finned lineage (the situation before teleost radiation) or even within bony vertebrates (the situation before the split of ray-finned fish and tetrapod). Partial sequencing of the genome of the elephant shark (*C. milii*), a cartilaginous fish, has already provided important insights into this last aspect.

Clearly, much more work and many more fish genome sequences are required to gain a more complete picture of the structure and evolution of fish genomes. This will help to decipher the evolutionary mechanisms having shaped genomes and organisms between different fish lineages. Fish population genomics provides important information on the genome-wide patterns of sequence variation between the individuals within species. Rapid progress in genome-sequencing technologies, with a huge reduction of sequencing costs and time, has already opened a new era of fish genomics. We will soon have a very panoramic picture of the link between genome plasticity, biodiversity, and speciation in fish, the much diverse group of extant vertebrates.

Glossary

Development The process of an individual organism growing organically; a purely biological unfolding of events involved in an organism changing gradually from a simple to a more complex level.

DNA promoter The site on deoxyribonucleic acid to which ribonucleic acid polymerase binds preparatory to initiating transcription of a gene or an operon.

Genetics The branch of biology that deals with heredity, especially the mechanisms of hereditary transmission and the variation of inherited characteristics among similar or related organisms.

Germline Sequence of germ cells that have genetic material that may be passed to a child.

Hematopoiesis The process by which the cellular elements of the blood are formed.

Invertebrates Animal without a backbone.

In vivo Biological processes or experiments occurring or carried out in the living organism.

Model organism A species that is extensively studied to understand particular biological phenomena, with the expectation that discoveries made in the organism model will provide insight into the workings of other organisms.

Mutagenesis Any event, usually intentional, that changes genetic structure; any alteration in the inherited nucleic acid sequence of the genotype of an organism.

Neurodegenerative Characterized by the gradual and progressive loss of nerve cells.

Oncogene A normal gene that may be activated by radiation or a chemical carcinogen to cause cancer.

Phenotype Observable characteristics of an organism including different traits. Phenotype results from the expression of an organism's genes and the influence of environmental factors.

Physiology The biological study of the functions of living organisms and their parts.

Positional cloning The identification of a gene and its isolation as a cloned deoxyribonucleic acid fragment, starting from knowledge of its position on a genetic map or chromosome.

Vertebrates Animal with a backbone.

Xenotransplantation The surgical transfer of cells, tissues, or especially whole organs from one species to another.

Introduction

For the past 100 years, the study of human biology and disease has relied on the use of model organisms. An understanding of the underlying genetic and cellular components of disease in a model organism can often be translated to the human system. Ideally, animal models should be similar to humans in terms of development, physiology, and genetics. Furthermore, an ideal model organism should be easy to maintain in large numbers, because this allows for more varied experimental maneuvers to confirm findings. However, working with so-called higher species is fraught with economic, ethical, and practical concerns. For example, housing and working with monkeys or other large mammals is not very cost effective. Even the laboratory mouse, which has become the most widely used vertebrate model organism, is limited by the high cost of housing, the large amount of space occupied by relatively few individuals, and the relatively slow generation time. By contrast, nematode worms and fruit flies are easy to maintain in large numbers for a very

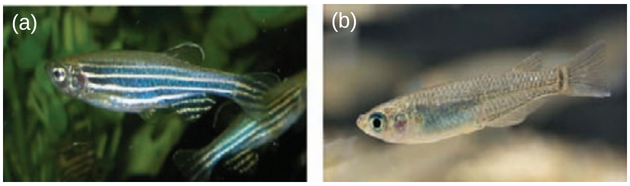

Figure 1 Fish model organisms. (a) Adult zebrafish. Photo by (http://commons.wikimedia.org/wiki/File:Zebrafisch.jpg). (b) Adult medaka, *Oryzias latipes* (Hamamatsu, Shizuoka, Japan). Photo by Azul. Photo by Seotaro (http://commons.wikimedia.org/wiki/File:Oryzias_latipes (Hamamatsu,Shizuoka,Japan,2007)-1.jpg).

low cost; however, as invertebrates they are less similar to humans. The goal is to find a model organism that is not only more closely related to humans, but also inexpensive to house and can be manipulated in large numbers. In the past decade, fish have emerged as promising model organisms that fit many of these criteria.

Fish, including zebrafish (*Danio rerio*) and medaka (*Oryzias latipes*) (**Figure 1**), are an advantageous model for many reasons. Like humans, fish are vertebrates, which often indicate that a given gene will function in a somewhat analogous manner in both species, especially as compared with nonvertebrate models. Their small size means that they can be housed in large numbers within small facilities. They reach sexual maturity in 3 months, providing a short duration for many experiments that require adults. Females can lay hundreds of eggs in 1 day and can mate multiple times a month. In addition, because the embryos develop outside the womb, one does not have to sacrifice the mother in order to access newly fertilized embryos. Because the embryos develop externally and are transparent, fish have become a premier model for *in vivo* visualization and manipulation of early embryonic development. Large-scale genetic screens, and the injection of morpholinos or transgenic constructs into embryos (**see also Cellular, Molecular, Genomics, and Biomedical Approaches**: Growth Hormone Overexpression in Transgenic Fish) at the one- to two-cell stage have allowed researchers to manipulate even the earliest processes in embryonic development (**see also Bony Fishes**: Zebrafish).

In this article, we will first describe some key techniques used to study disease processes in fish. Then we will review some of the more important discoveries about disease in different organ systems. Throughout the discussion, the term 'fish' will imply both zebrafish and medaka. Although the two are not interchangeable, for the purpose of this article, we will focus on fish in general as the model organism of interest.

Forward Genetic Screens

One major utility of the fish is the capacity to perform forward genetic screens which rely on the principle of working from a phenotype to gene discovery. There are three ways to create mutations in which permanent genomic changes occur in the fish germ stem cells, including mutagenesis by exposure to a chemical (ENU, *N*-ethyl-*N*-nitrosourea), X-ray, or an insertional virus. These three methods create random germline mutations, which allow the altered DNA to become inherited in subsequent generations. The embryonic offspring of these animals are then screened to look for ones that have a phenotype of interest. This can be anything from a lack of blood cells, to an enlargement of the brain cells. Once an interesting mutant is found, the gene affected in that mutant is identified through techniques such as positional cloning. Most commonly, these screens are designed to identify genes or pathways that are required for various aspects of embryonic development, but more recently are being applied to adult phenotypes. Forward genetic screens have been used to identify fish mutants with abnormalities resembling human diseases such as anemia, congenital heart malformations, arrhythmic heartbeats, and muscular dystrophy. Subsequent cloning of the mutants has identified the genes specific to each disease and has provided insight into the mechanisms of the human disease. The identified gene products may also provide potential therapeutic targets.

Reverse Genetics

Reverse genetics involves perturbing a gene of interest and looking for the phenotypic consequences. A common reverse genetic system is gene knock-out in which sections of DNA are replaced, thus producing nonfunctioning gene products. This is accomplished by the manipulation of embryonic stem cells lines in culture that are then re-introduced into newly fertilized mouse embryos. Embryonic stem cells in the fish have been difficult to successfully culture and manipulate (**see also Cellular, Molecular, Genomics, and Biomedical Approaches**: Culture of Fish Cell Lines), making this technique more challenging. Several new technologies have been developed that allow scientists to attempt reverse genetics in the fish model. TILLING, or targeting induced local lesions in genomes, was one of the first techniques used to create a targeted mutant for a human disease gene of interest. Adults are exposed to chemical mutagens, and the DNA from their germ cells is directly sequenced to identify mutations in the gene of interest. A new technology utilizing zinc-finger nucleases also gets around the caveat of needing embryonic stem cells to create mutants. Zinc finger proteins are designed to recognize a specific DNA sequence. Once bound, a nuclease attached to the zinc finger induces a break in the DNA, forcing attempted repair of the DNA. This repair often is incorrect and leads to mutagenic insertions or deletions at the site of the double stranded break. This is an exciting new technology that will greatly advance the study of human disease in fish. Reverse genetics has been used to mimic many human disorders, including hematopoietic diseases and neurodegenerative disorders, including Huntington's disease. Such disease models have exciting potential for medical research, for example, in the identification of good drug targets and in screening for small molecules that ameliorate disease progression or severity.

Morpholino Gene Knockdown

If a gene involved in a human disorder is already known, understanding its role in embryonic development can often give insight into that gene's function. One method of doing this is to knock down the gene's expression during embryonic development using morpholinos, antisense oligonucleotides that block gene expression by interfering with the translation of the gene product either by preventing initiation or by altering RNA splicing. Morpholinos are useful to study the function of a gene in embryo development by injecting the compounds into a one–two-cell stage embryo and comparing the growth and differentiation to that of untreated embryos. Some labs have even begun doing morpholino screens to better define certain signaling pathways. Morpholino gene knockdown has been useful in better understanding the genes involved in many human neurodegenerative diseases. Genes implicated in Alzheimer's disease and Parkinson's disease (PD) have been studied using this method, which has led to a better understanding of the functional role these genes play in both normal and diseased patients.

Transgenesis

In some cases, a gene is known to be associated with a disease but little is known of its function. One useful technique in the fish is transgenesis, in which expression of a gene of interest can be forced in a specific tissue of interest, allowing for detailed studies of that gene's function *in vivo*. This technique requires two major components: (1) the altered gene itself – in cancer studies, these are often oncogenes, which are mutated forms of genes that are responsible for proliferation, a prerequisite for most human cancer and (2) a DNA promoter, which allows for expression of that gene in only the tissue of interest. Transgenics are used to model diseases *in vivo* and watch their progression in real time. Many human cancers including leukemia and melanoma have been modeled in fish, allowing for a better understanding of disease initiation, metastasis, and treatment. Transgenics can also be used to tag specific cell types with a fluorescent protein (**Figure 2**). Not only can red blood cells, lymphocytes, neurons, and even entire organs be labeled, but fluorescently labeled cancer models have also been created. This technique has improved imaging of individual cells in adult fish, enhancing our ability to track cell proliferation, honing, and migration *in vivo*.

Transplantation

Transplantation is another technique often used in the fish model to study cancer tumorigenicity and bone marrow/hematopoietic stem cell (HSC) biology. Transplantation of cancer cells allows us to track individual cell migration and proliferation and to test the effectiveness of drugs on preventing these cancerous processes. In addition, the zebrafish has emerged as a powerful tool to find ways to improve HSC transplants, often used as a treatment for diseases such as leukemia. Transplantation allows us to test different variables affecting bone marrow engraftment after such treatments.

Researchers have also begun using the commonly farmed tilapia (*Oreochromis niloticus*) fish to study type I diabetes. Scientists have created transgenic tilapia carrying a humanized insulin transgene that, when grown to maturity, produce human insulin. The hope is that these transgenic fish can be used for xenotraplantation of insulin across species.

Chemical Biology

Most recently, the utility of fish for large-scale chemical screens has been realized. Thousands of embryos can be exposed to different chemicals from small molecule libraries and screened for interesting phenotypes. The fish is an ideal organism for this type of screen because water-soluble compounds can be directly added to the fishwater. In addition, female fish lay hundreds of embryos a day, permitting high-throughput *in vivo* screening, which is largely cost and space prohibitive in the murine system. In a single day, thousands of embryos can be exposed to hundreds of chemicals for effects on a variety of development pathways. Most often, screens are

used to better characterize embryonic phenotypes or for the purposes of drug discovery. Using chemical screens in combination with transplantation studies has allowed researchers to look for compounds that increase the success rate of bone marrow transplants or that can specifically inhibit growth of certain types of cancer cells. Chemical screening in zebrafish has also expanded to include *in vivo* toxicological screening of pharmacological compounds prior to preclinical human studies.

In Vivo Imaging

The ability to look at individual cells and organs *in vivo* during development is extremely beneficial for disease modeling. There is no other model organism besides the fish in which one can watch the development of vertebrate tissues such as blood, spinal cord, and bones in real time. Fish embryos are also useful for studying the initiating events in cancer formation. For many cancers, we do not know when cells first become cancerous, or what they do at the earliest stages. Where and when do they become diseased and begin migrating, and does this metastasis occur in specific locations? Using transgenics, cancer cells can be tagged with green fluorescent protein (GFP) allowing even the most primitive cancer cells to be visually tracked in a living animal.

In contrast, evaluation of adult processes in zebrafish has been limited due to the opacity of the mature animal. Inspired by studies of blood flow and vascularization in the naturally occurring glass catfish (*Kryptopterus bicirrhis*), researchers have recently created a nearly transparent adult zebrafish termed *casper* (**Figure 3**), which will allow for the power of the zebrafish system to be utilized for a broad array of adult studies. Named *casper* for its ghost-like clarity, scientists have been able to use this mutant fish to visualize internal tumors, and document cancer cell migration in adult fish cancer models. These transparent fish have also been used to study the engraftment of blood stem cell, a clinically important process to understand to improve bone marrow transplants in humans.

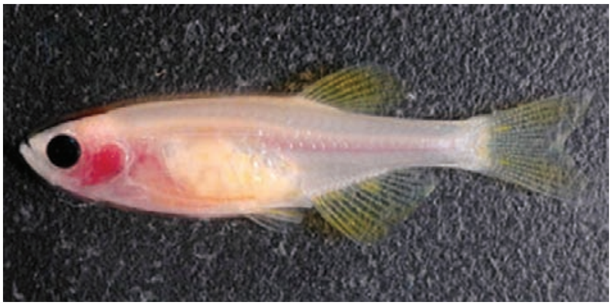

Figure 3 *Casper* zebrafish mutant. Photo courtesy of Richard White, Dana-Farber Cancer Institute, Boston MA.

Research in the past decade has proved that, in conjunction with the described experimental techniques, fish are an excellent model organism to understand many aspects of human biology. While fish research has only been underway for several decades, it has already contributed to the understanding of a number of human diseases. Next we will look at some of the more important discoveries regarding disease of organ systems, including blood, heart, kidney, brain, muscle, and skin.

Blood

Hematopoiesis, the formation of blood, involves differentiation of blood stem cells into different mature blood cells utilized for oxygen exchange, immune response, and clotting. Disruption of any of these processes is at the root of many human blood diseases and disorders. The fish is a powerful model to study hematopoiesis, as the genetic regulation and blood cells types are highly conserved from fish to humans. Over 50 hematopoietic mutants have been characterized with phenotypes that can be divided into five classes: bloodless, blocked progenitor proliferation, blocked progenitor differentiation, hypochromia, and photosensitive blood (**see also Blood**: Cellular Composition of the Blood and Erythropoiesis in Fishes).

Anemia

To date, most insight has been gained into red cell function, such as iron metabolism, heme synthesis, and globin expression. This is significant because one of the most common human hematopoietic disorders is anemia, a deficiency of red blood cells. By modeling different anemias in the fish, a much more detailed understanding of the causes of the multiple forms of human anemia can be found, and the feasibility of potential therapies can be evaluated.

One specific example is the human disease, sideroblastic anemia. Using forward genetics, scientists identified a mutant fish, sauternes (sau), which presented with immature circulating erythroid cells, a characteristic of the human condition. Using positional cloning, a mutation of the gene ALAS2 (Delta-aminolevulinate synthase 2) was found on chromosome 9. Likewise, it is known that sex-linked congenital sideroblastic anemia in humans is due to a mutation in the ALAS2 gene. This mutant fish model for human sideroblastic anemia can be used to study the enzyme's function and its role in anemia, with the hope of finding more effective treatments.

Hematopoietic Stem Cells

HSCs are another area of intense scientific study. For several decades, transplantation of human HSCs into patients with defective hematopoiesis has been used as a therapy to repopulate the patient's hematopoietic system. This is most commonly used for patients with cancers of the blood system. However, HSC transplant is still a highly toxic procedure, in part because it takes several weeks for the transplant to engraft in the recipient and there is a limited amount of HSCs available to patients. Researchers hypothesized that a better understanding of how to increase the total number of HSCs in fish could lead to possible improvements in bone-marrow transplants in humans. A team of investigators followed up this hypothesis and used the fish to perform a chemical screen looking for chemicals that either increased or decreased HSCs in the fish embryo. In the screen, they found that prostaglandin E2 increased the number of HSCs. After pretreating mouse HSCs with prostaglandin prior to transplantation, they found an expansion of functional HSCs, which led the researchers to hypothesize that prostaglandin E2 could be used as a therapy for patients needing bone-marrow transplants. The clinical trials for prostaglandin are currently underway. This example shows how using a zebrafish screen led to a discovery of a novel role for a chemical, which ultimately has led to a Food and Drug Administration (FDA)-approved clinical trial on human patients.

Leukemia

Cancer of blood, or leukemia, is a broad class of diseases, which are incompletely understood. Leukemia is marked by abnormalities of the bone marrow in which there is overproduction of cells called blasts, which are immature red, white, or platelet blood cells (**Figure 4**). While there are some treatments available to leukemia patients, little is known about why the disease initiates and how it progresses. Fish allow us to model leukemia to better understand what happens in the earliest stages even before diagnosis is possible. Researchers have been able to model types of human leukemias in fish using the transgenic approach, in which various oncogenes known to be important in human leukemia can be studied. Some examples using this approach include: (1) the rag2 promoter driving either the myc oncogene, or the

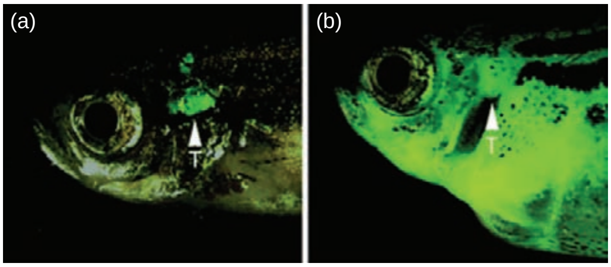

Figure 4 Leukemia transgenic adult *rag2-EGFP-mMyc* zebrafish. (a). Normal GFP expression in the thymus of the control rag2-GFP fish. (b). GFP-labeled leukemic lymphoblasts in the leukemia fish model (rag2-EGFP-mMyc). Arrowheads mark location of the thymus (T). Reproduced from Langenau *et al.* (2005) 102(17): 6068.

Notch1/bcl2 oncogenes, results in T-cell acute lymphoblastic leukemia (T-ALL), (2) the beta actin promoter (expressed in most cells) driving the runx1 oncogene leads to early B-lineage acute lymphoblastic leukemia, and (3) the beta actin promoter driving the KRAS oncogene leads to a myeloproliferative disorder replicating human chronic myelomonocytic leukemia. Other oncogenes are formed when two separate genes translocate and become expressed jointly. The BCR/ABL oncogene has been used in fish to model human chronic myeloid leukemia, and the TEL-AML1 oncogene is used to model acute lymphoblastic leukemia.

Heart

Over 40 cardiovascular mutants have been defined in fish, and are divided into two groups: defective cardiac formation or cardiac function.

Cardiac Formation

Malformations of the heart have devastating effects in human patients. While surgeons can repair holes, replace valves, and even transplant new hearts, what causes the original deformations is unknown. Using a forward genetic mutagenesis screen, a zebrafish mutant gridlock was found that has a heart defect resembling the human condition of coarctation of the aorta, a congenital malformation of the heart, for which, in many cases, the cause is unknown. The fish was found to have malformation of the aorta, leading to decreased blood flow to the tail. This is functionally similar to human patients, in which malformations of the aorta restrict blood flow to the lower parts of the body. Because the early development of the human disease is difficult to study, the fish model is useful because embryos known to carry the gridlock defect can be studied from the moment they are fertilized to allow for more insight into the initiating steps of the disease. In addition, a chemical screen was performed on this model of coarctation of the heart revealing two chemicals, GS4012 and GS4898, which were able to completely rescue the mutant without causing developmental defects. In addition to the coarctation model, other mutants of clinically relevant cardiac malformations of heart fusion and size have been created. The mutants miles apart (mil) and bonnie and clyde (bon) have disrupted heart fusion, causing differentiation and development of two hearts, a phenotype resembling the human condition of cardia bifida. Mutants of other cardiac malformations include cloche (no endocardium), valentine (large heart), and heart and soul (small dense heart).

Cardiac Function

Diseases of heart malfunction are critical to understand. If the heart beats too fast, it can lead to heart failure; if the heart beats too slowly, blood cannot supply sufficient oxygen needed by all organs. Scientists have also been able to use the fish as a model to study cardiac function. In an example using transgenesis, a cardiovascular research team developed a unique assay to quantify the embryonic heart rate in fish. The researchers created a transgenic fish in which green fluorescent protein (GFP) was expressed exclusively in the myocardium. They then developed a computer program that could analyze and calculate the heart rate in living fish. Use of this technique is exciting for groups studying a variety of heart-rate disorders. Atrial fibrillation is the most common human cardiac arrhythmia, characterized by the heart beating too quickly. In some cases, this disorder is familial; however, little is known about its cause. Another disorder is supraventricular tachycardia, which is characterized by a sudden, almost instantaneous increase in heart rate. In order to gain insight into these conditions, forward genetic screens have been performed to isolate mutants with abnormalities in heart rate. The fish mutant breakdance (bre) has an arrhythmia in which the ventricle beats only with every second atrial contraction, resembling the human Long QT syndrome. The human short-QT syndrome has been modeled in the fish mutant reggae (reg) that shows cardiac fibrillation due to accelerated cardiac repolarization. Different mutations in the same gene, Zerg, are responsible for both phenotypes. Other cardiac function mutants include: slow mo (slow heart rate/sinus bradycardia), dead beat (weak ventricle contractility), beach bum (weak contractility of both chambers), tremblor (fibrillation), and ping pong and yoyo (retrograde flow and regurgitation of blood).

Kidney

There are many diseases of kidney tissues, some of which involve the formation of fluid-filled cysts in the kidney tubules. Autosomal dominant polycystic kidney disease (ADPKD) is one such common genetic human disease that often leads to renal failure. While extensive studies have been done to elucidate the mutations of the PKD1 gene that are involved in the human disease, it is still unclear how and why these fluid-filled cysts develop. Recently, a mutagenesis screen in zebrafish identified three genes that encode components of intraflagellar transport particles needed in cilia formation. It has been proposed that the primary cilia act as flow-sensing organelles in the kidney cells. Once flow in the tubules is optimized, the cilia can signal the kidney cells to stop replicating. In mutated forms, however, the cilia do not signal properly, leading to outgrowths of the kidney that develop into cysts (**Figure 5**). The results of these experiments suggest that mutations in these ciliary genes are one major cause of PKD. There are multiple kidney diseases involving cyst formation that likely may also be linked to these ciliary genes. In addition, because the embryos are transparent, researchers are able to visualize the early signs of cyst formation in vivo well before they are visible in other model systems.

Neuroscience

Neurodegenerative Disease

Huntington's disease is an inherited neurodegenerative condition characterized by cognitive defects, dementia, and psychiatric dysfunction. While extensive research has identified a mutation in the human protein, huntingtin, the precise function of this gene remains poorly understood. Researchers have recently identified a zebrafish homolog to the Huntington's disease gene, called zhd, which encodes the protein huntingtin. Identification of this gene will allow researchers to understand its function in normal development, using morpholino knockdown. In addition, a knockout of this gene (using TILLING or zinc fingers) can help to identify mutant fish, which exhibit characteristics of patients with Huntington's disease.

Alzheimer's is a neurodegenerative disease caused by fragments of a protein, amyloid precursor protein (APP). A fragment of APP called amyloid beta peptide can aggregate and form amyloid plaques, which accumulate in brain neurons. Pen-2 is an enzyme required for the formation of the amyloid B protein plaques. Researchers used the zebrafish to better understand the role of Pen-2 in Alzheimer's development by designing a morpholino to block transcription of the Pen-2 gene. Knockdown of Pen-2 had a negative effect on cell survival indicated by an increase in apoptosis. Because apoptosis in the adult nervous system is often an initiating step in many neurodegenerative diseases, the fish provides a useful tool for deciphering this complex signaling pathway in the origins of Alzheimer's disease. While it is still unclear how Pen-2 affects the formation of plaques in adult neurons, research focused on better understanding its normal function will enhance our knowledge of brain development, neuronal apoptosis, and the signaling mechanisms involved in plaque formation leading to Alzheimer's.

PD is another neurodegenerative disease affecting 1 in 800 people. Patients suffer from physical rigidity and tremors in addition to cognitive psychological abnormalities. Previous studies have shown that PD is, in part, due to loss of dopaminergic cells; however, we still do not know exactly why the neurons die. Aspects of PD can be induced by mutations in the A2A adenosine receptor (Adr) genes, or due to the administration of a neurotoxic drug called 1-methyl-4-phenyl-1,2,4,5-tetrahydropyridine (MPTP) that causes degeneration of dopaminergic cells. In the past 2 years, zebrafish homologs to the Adr genes have been identified. The function of these genes in early development was studied using morpholino technology, which induced loss of dopaminergic neurons

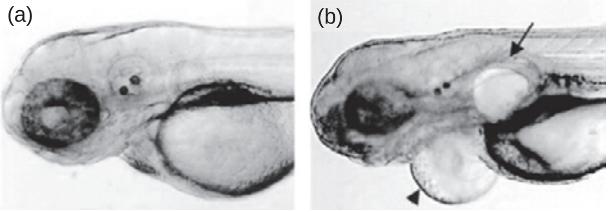

Figure 5 Kidney cysts in zebrafish embryos. (a) Control embryo. (b) The arrow in (b) shows a kidney cyst, and the small arrowhead shows pericardial edema. Reproduced from Sun and Hopkins (2001).

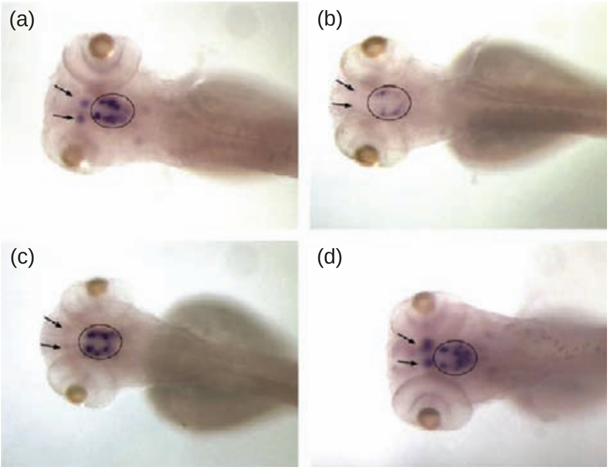

Figure 6 Caffeine protects dopaminergic neurons from MPTP-induced neurotoxicity. 5 dpf embryos hybridized with *dat* probe, staining ventral diencephalon neurons. (a) Untreated control embryo. (b) Drug-treated embryo with 40 μM MPTP shows decreased neuronal staining. (c) Embryo treated with 10 μM caffeine and also 40 μM MPTP shows increase in staining compared to MPTP treatment in (b). (d) Embryo treated with 10 μM caffeine shows normal staining. Black arrows indicate bilateral pretectal cluster of neurons. Reprinted from Boehmle *et al.* (2009) Identification of zebrafish A2 adenosine receptors and expression in developing embryos. *Gene Expression Patterns* 9(3): 144.

similar to that effected by MPTP. Because caffeine is a known A2A AdR antagonist, researchers hypothesized that caffeine would be neuroprotective against MPTP, and this was found to be selectively true – the results showed the caffeine protected ventral diencephalic but not pretectal neurons (**Figure 6**). The zebrafish Parkinson's model is the first description of following the disease state from its earliest stages. It also further implicates AdR antagonists as promising therapeutic treatments.

Muscle

Muscular Dystrophy

Muscular dystrophy is an inherited disease of skeletal muscle in which abnormalities of several muscle proteins, such as dystrophin and dystroglycan, contribute to the disease. A better understanding of how these proteins cause muscular degeneration would provide therapeutic opportunities. Recently, a zebrafish mutagenesis screen was performed to isolate mutants with defects in muscle formation. One mutant, referred to as sapje (sap), was confirmed to resemble many aspects of the disease. Positional cloning of the affected gene revealed a mutation in the dystrophin (DMD) gene, one of the proteins known to be affected in human patients. The sap mutant was then studied during early embryonic development to gain insight into the origins of muscular dystrophy. The muscles of human adult patients suffering from DMD show tearing and scaring along the entire muscle region. However, the sap mutant showed that dystrophin is specifically lost from the ends of the muscle fibers in developing embryos. Because we cannot assess where damage is occurring in developing humans, the zebrafish model suggests that muscle attachment failure to the cytoskeleton is also a major contributor to DMD. Other dystrophic mutants reflecting various aspects of MD have been developed, and include softy, unresolved, and candyfloss (a model of congenital muscular dystrophy (MDC1A).

In addition to studying mutants, researchers also used morpholino technology to further examine the function of the genes involved in muscular dystrophy. Dystroglycan is another component of the dystrophin-associated protein complex (DAPC), which is found at the membrane of skeletal muscle fibers and provides a structural link between the cytoskeleton and the extracellular matrix. Downregulating the dystroglycan gene during embryonic development demonstrated that the protein is essential for normal differentiation of muscle fibers. While loss of dystroglycan does not cause muscular dystrophy, it does result in the inability of the muscle fibers to form the normal organization of proteins required for proper muscle contraction. It is likely that defects in dystroglycan can be linked to more rare forms of the disease such as Fukuyama-type muscular dystrophy.

Muscle Tumors

Little is known about the origins, progression, or treatment of muscle cancer. The zebrafish has recently emerged as a tool in understanding a type of muscle tumor called rhabdomyosarcoma. Activation of the RAS oncogene pathway is known to occur in some human muscle tumors. Studies using a transgenic fish ubiquitously expressing the kRAS oncogene under a beta-actin promoter resulted in tumor formation resembling human rhabdomyosarcoma. The childhood form of this disease is especially devastating; at the time of a metastatic diagnosis, less than 25% of patients surviving past 5 years. While the rag2 promoter described in leukemia is known to be specific to T cells, it was recently discovered that it also is expressed in embryonic zebrafish muscle cells. Surprisingly, linking the kRAS oncogene to the Rag2 promoter created a fish model of childhood rhabdomyosarcoma. The reasons for this remain unclear. Using this model as a basis for research, further evaluation of human rhabdomyosarcoma reported that the majority of human rhabdomyosarcoma tumors also shows an activated RAS pathway. Researchers hope to use the zebrafish model to further explore the specifics of the RAS pathway responsible for tumor progression.

Skin

Pigmentation

An everlasting puzzle in human biology surrounds the question of the genetic origin of skin color: why do people of different races have different skin pigmentation, and why do people within those races show varying degrees of coloration? It is known that variations of skin pigmentation are due to differences in the number, density, and size of melanosomes, the pigmented organelles within melanocytes. Previous to studies using zebrafish, it was largely unknown what genes cause these variations between populations. A zebrafish mutant named golden shows delayed and reduced production of the melanin pigment (**Figure 7**). This mutant resembles light-skinned humans. Positional cloning revealed the golden mutant was caused by a mutation in the nckx5 gene, a homolog to the mammalian slc24a5 gene. Functional conservation of these genes was supported by injecting human slc24a5 messenger RNA (mRNA) into the golden mutant, resulting in rescued melanin pigmentation. Analysis of the human golden gene showed that, at the 111-amino-acid position, there could be either a threonine or an alanine variant, called a single nucleotide polymorphism (SNP). Comparing this to human population studies, they reported that nearly 99% of European Americans expressed the Thr allele, and close to 95% of African, indigenous American, and East Asian populations expressed the Ala allele. These data revealed that this single gene accounts for nearly 40% of human skin pigment differences. The fish model provided an exciting example of how a mutagenesis screen can be used to first find a phenotype of interest in the fish and then use the fish gene to determine the human homolog and its function.

Fish provide a unique tool for studying disorders of skin pigmentation. Fish have three distinct pigment cell types: melanophores (the melanin-containing cells called melanocytes in humans), xanothophores (give the fish a slight yellowish hue), and the iridophores (contain the reflective platelets on fish skin). However, the most studied of these pigment types in human disease are the melanophores. Albinism in humans has many forms due to two major types of melanocyte defects. In one set, patients are entirely missing the cell type (melanocytes) that produce melanin, and, in the other, the melanocytes are present but are defective and unable to produce the melanin pigment. A fish model of the former was created in a fish mutant termed nacre (**Figure 8**). Nacre is a homolog to the human MitF, a gene known to be required for eye and pigment cells in the mouse and human. The

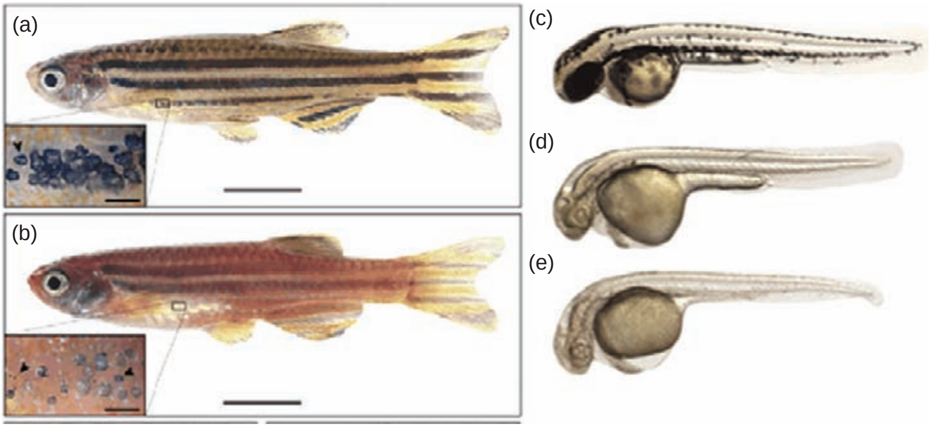

Figure 7 Phenotype of *golden* adult and embryonic zebrafish. (a) Adult wild-type zebrafish and (b) adult zebrafish *golden* mutant. Insets show melanophores (arrowheads). Figure 8 Phenotype of (a) adult WT zebrafish and (b) adult nacre mutant zebrafish.

nacre mutant shows an absence of melanocytes throughout development. Other types of albinism result from defective melanocytes that cannot produce pigment. This disorder is phenocopied in a mutant fish named *sandy*, which has defects in the melanin-producing enzyme tyrosinase. Modeling human pigmentation disorders in the fish will allow scientists to gather more information about embryonic development and possible therapies for more detrimental disorders of this class (**see also Cellular, Molecular, Genomics, and Biomedical Approaches**: Pigment Genes and Cancer Genes and **The Skin**: Coloration and Chromatophores in Fishes).

Melanoma

Melanoma is a particularly devastating cancer, which arises from melanocytes in human skin. With little known therapy, once metastatic disease is diagnosed, there are nearly no effective available therapies. Understanding the beginning stages of melanoma are crucial to finding methods to prevent cancer cells from forming, or delaying the metastasis of the disease. To gain to insight into the origins of this disease, researchers have studied the two hits necessary to produce most cancers. One hit is a mutation of a gene that causes excess cell proliferation, a hallmark of most cancers. In human melanoma, this is usually due to mutations in the BRAF oncogene. The second hit is something that prevents cells from undergoing cell death (apoptosis). In melanoma, this second hit often comes from loss of the p53 tumor suppressor gene. The normal function of p53 is to signal cells to apoptose when cell programming goes awry. The p53 null mutant is unable to send this apoptosis signal, thus allowing the abnormal oncogenic cells to multiply. Using this information, scientists created a melanoma model in fish by expressing the BRAF oncogene under the melanocyte-specific MitF promoter in the background of a p53 null fish. Nearly 100% of these transgenic fish eventually form melanoma tumors that histologically resemble human tumors (**Figure 9**). These fish mutants are being studied extensively with the hope of finding therapies for the growth and metastasis of melanoma cells (**see also Cellular, Molecular, Genomics, and Biomedical Approaches**: Pigment Genes and Cancer Genes).

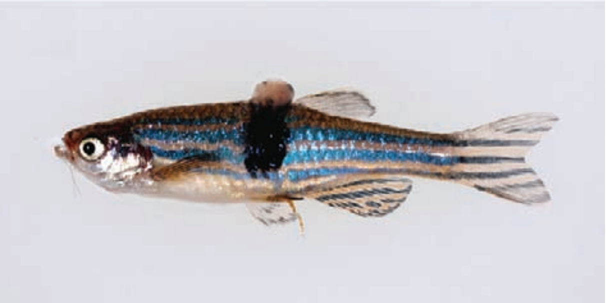

Figure 9 Adult zebrafish melanoma model. Photo courtesy of Richard White, Dana-Farber Cancer Institute, Boston, MA.

Behavior

Addiction

While a relatively new field, studying psychological or behavioral traits in the zebrafish is beginning to emerge as a useful adjunct to mammalian studies. Researchers studying diseases of addiction, most notably to alcohol and nicotine, have begun using the fish as a model organism. Scientists have been able to accurately mimic the enhanced dopamine levels found in human patients repeatedly exposed to addictive drugs. A forward genetic screen produced a fish mutant, too few, that cannot produce sufficient dopaminergic and serotonergic neurons in the forebrain. After multiple pre-exposure to morphine, when given the choice between normal or morphine-containing water, normal fish show a preference for the drug water. The too few morphant, however, does not show this same preference as their wild-type siblings, implicating that choice behavior and addiction is partially mediated through the dopaminergic and serotonergic neurons in the central nervous system.

Sleep

Sleep disorders such as narcolepsy are in the beginning phases of being modeled in fish. The neuropeptide hypocretin is a key regulator of sleep in humans. A fish mutant was created in which there is a mutation for the gene encoding the receptor of this neuropeptide. These fish display a contrasting phenotype to narcolepsy. Rather than excessive sleepiness or cataplexy, the fish suffer from short and fragmented period of sleep in the dark. Understanding what genetically separates these abnormal patterns of fish sleep from narcolepsy will better our understanding of both disorders, and possibly lead to novel therapies. Current research is focused on delineating the normal role of sleep, its cycle, and modeling other sleep-associated disorders in fish.

Mood

Researchers are also interested in studying different mood behaviors in fish. Most recently, a novel aggressive mutant, speigel, was identified. It appears that serta, the serotonin transport gene, plays a role in the speigel mutant. Current experiments are testing whether selective serotonin reuptake inhibitors affect the aggressive behavior in speigel. Future studies hope to evaluate if other behavioral traits can also be linked to specific genetic mutations.

Future

The field of fish research has provided us with many discoveries about human disease over the past decades and will undoubtedly continue to grow and expand in the future. It is likely that significant areas of research will further involve functional genomics, chemical screening, and cancer genomics. In the post-genomic era, where the genomes of many species have now been fully sequenced, a major challenge is to try and understand the function of these gene sequences. The rapidity of transgenesis and increasing tools in reverse genetics will allow for high-throughput analysis of understanding gene functions that are conserved across vertebrate species. In addition, until this point, the capacity for chemical screens in the fish has been restricted to relatively limited small molecule libraries. However, with increasing automation and novel assay design, truely high-throughput screens (i.e., 50000–500 000 compounds) will be feasible in the near future. This will allow for a comprehensive examination of in vivo phenotypes induced by structurally diverse small molecules. Lastly, 'deep' resequencing of cancer genomes is rapidly accelerating, but the importance of these newly discovered gene mutations is largely unknown. Utilizing reverse genetics and transgenesis, the zebrafish is well poised to allow for detailed modeling of novel cancer genes in a high-throughput, relevant model organism.

Introduction
Fish Transgenesis
Further Reading

Glossary

Antifreeze proteins Small proteins secreted into the blood of some species of Arctic fish to prevent their blood freezing in the Arctic winter seas. Some Antarctic fish also produce antifreeze but they are quite different in action from the antifreezes of Arctic fish and have clearly evolved separately. Antifreeze coding genes have been isolated from some fish species such as ocean pout and winter flounder and used transgenically in attempts to make Atlantic salmon resistant to freezing.

Diploid Having two complete chromosome sets.

Exon A part of the DNA sequence of a gene which is expressed in the protein. Following initial transcription, intron sequences are spliced out and the exon sequences spliced together to produce the relevant messenger RNA.

Gene A hereditary unit consisting of a single strand of DNA occupying a specific locus within a chromosome, and in many cases carrying the genetic code for a protein.

Gene expression The production of a phenotypic trait by a gene. This involves the transcription of the gene into RNA and subsequent translation of the RNA into protein.

Gene integration The incorporation of a DNA gene sequence into the chromosomal DNA of the cell nuclei following the gene's introduction into the cell.

Gene manipulation Any artificial work with chromosomes or genes, including gene sequence isolation, modification, cloning, and subsequent use in transgenesis. See transgenesis.

Genetic engineering Essentially synonymous with gene manipulation (see transgenesis).

Genome The entire set of genes and noncoding DNA present in the haploid cell of a particular organism, but not including the separate mitochondrial genome.

Genotype The genetic constitution of an organism. Only part of the genotype is expressed in the phenotype, since recessive alleles present in a heterozygous state are not expressed in the phenotype.

Germ line transmission Passage of a gene through the eggs and sperm from parent to offering. This will normally only occur if the gene in question is present in the chromosomal DNA of the gonads of the parents.

Green fluorescent protein (GFP) A widely used reporter gene used in transgenesis. The original was derived from the genome of a jellyfish, and the protein product shows green fluorescence without the need for activation, substrate provision, or the death of the animal.

Haploid A genetic state in which a cell or organism possesses only one copy of each gene and chromosome. Sperm and egg cells are haploid, and fertilization of the egg by the sperm restores diploidy.

Intron A part of the DNA sequence of a gene which is not expressed in the protein but spliced out between transcription and translation.

lac Z A gene from the bacterium *E. coli* which is often used as a reporter gene in work with fish. When an appropriate development procedure is used, the lac Z provides a blue color. Only of use with dead material. lac Z means the Z gene from the lac operon, a small cluster of genes in the bacterium which act as a unit.

Luciferase A reporter gene derived from a species of firefly. For luminescence to show, the substrate luciferin is required.

Meganuclease A particular category of restriction endonuclease enzyme with a very long DNA target sequence.

Morpholino A molecule used to knock down gene translation. This is achieved by blocking access of ribosomal initiation complex to an mRNA with modified antisense oligomers, and thus preventing from making a targeted protein.

Mosaic expression Nonuniform expression of a transgene in an organism, implying that only some tissues carry copies of the transgene, or that the expression is only activated in certain tissues. The latter situation is more commonly referred to as tissue-specific expression.

Phenotype Observable characteristics of an organism including different traits. Phenotype results from the expression of an organism's genes and the influence of environmental factors.

Polar body The tiny cell released by the oocyte during reduction division. Although technically a cell, the polar body has almost no cytoplasm, but contains a nucleus. Triploid induction may involve retention of one of the polar bodies, induced by pressure or temperature shock.

Primary oocyte A stage in vertebrate egg production prior to the two rounds of division which produce the egg. The primary oocyte has four copies of each chromosome, the secondary oocyte following the first reduction division only two, and the egg following the second reduction division only one. These reduction divisions each involve the release of a polar body.

Prion A misfolded protein particle capable of causing diseases such as mad cow disease (BSE). The misfolded prion protein is capable of inducing similar misfolding to the relevant proteins of the host, thus causing disease. The genes coding for the prion protein are present in the genome of the affected organism.

Promoter The upstream sequence of DNA which regulates the expression of the downstream coding sequence of the gene. The promoter may sometimes be as big or bigger than the gene itself. A so-called minimal promoter is the length of the promoter required to achieve expression of the gene, but without additional positive or negative elements.

Red fluorescent protein (RFP) An alternative to the more commonly used reporter gene (GFP). Like the latter, RFP is derived from a jellyfish and needs neither substrate nor activation for fluorescence.

Reporter gene A gene sequence used to provide a signal, usually visible, that a gene sequence is present in a cell or organism after transgenesis. Common examples are lac Z, GFP and RFP genes, and the luciferase gene.

Restriction enzyme Endonuclease enzymes which are highly specific and cut DNA only within a particular target sequence.

Sleeping Beauty transposon A transposable element developed within the laboratory of Prof. Perry Hackett in the USA. The original inactive element was recovered from a salmon genome, and then returned to full active transposable activity by a series of targeted mutations. It has come to be widely used to facilitate gene integration during transgenesis.

Tetraploidy The genetic state of a cell or organism in which four copies of each chromosome are present, usually two being of paternal origin and two of maternal origin. Tetraploidy can sometimes occur naturally as a result of a failure of a nucleus to divide after DNA replication and mitosis. Tetraploid organisms may be sterile, but are not invariably so.

Transgenesis Transfer of new genetic material to an organism or cell, or between organisms. The resulting organisms are then said to have been genetically manipulated (GM).

Transposon A DNA element, often a few kilobases in size, which can insert itself within a genome or move from one site to another within a genome.

Triploid Having three complete chromosome sets.

Introduction

Transgenesis is the introduction of a novel gene into the genome of an organism. Such organisms are then referred to as genetically manipulated or GM. When it became possible in the 1980s to isolate and clone genes from a variety of organisms, the possibility of transgenesis arose, and this was initially achieved in mice and *Drosophila.* Clearly, the target of any transgenesis program is to have the novel gene of interest isolated, introduced into the cells of the recipient organism, integrated into the chromosomal DNA, and eventually transmitted to the progeny of the organism as part of the normal genetic endowment. Finally, it is expected that the relevant gene will be expressed in the cells and tissues of the recipient organism and its progeny. Thus, there are various steps in the progression between gene isolation and having a batch of transgenic animals, and these are usefully referred to as introduction, incorporation, transmission, and expression.

Following success with all of these stages in mice using a rat growth hormone gene, leading to the production of rapidly growing enlarged GM mice, work started in a few laboratories to achieve the same end point with fish. This initial ambition was realized with fish of various species such as common carp (*Cyprinus carpio*), rainbow trout (*Oncorhynchus mykiss*), zebrafish (*Danio rerio*), and medaka (*Oryzias latipes*).

Chromosome manipulation refers to the artificial alteration of the ploidy of an organism, that is to change the chromosome number from the normal state to haploidy, triploidy, or tetraploidy. It is chiefly of interest in fish as a means of producing triploid fish, which are most frequently sterile and sometimes also grow faster than their diploid siblings.

Fish Transgenesis

Gene Isolation

It has been known since Mendel's time that hereditary factors exist within the nuclei of all living cells, and with the discovery of DNA as the genetic material and its structure as a double helix of nucleotide pairs, it became clear that a gene was a length of DNA, usually of a few thousand bases. In order to appreciate the problems of isolating genes, it is necessary to step back and consider for a moment the structure of a gene. As shown in **Figure 1**, it consists of a linear DNA sequence within a DNA double helix. The gene is only one strand of the double helix, referred to as the sense strand, while the other strand to which it is hydrogen-bonded is referred to as the anti-sense strand. The strand has polarity and runs from a $3'$ end to a $5'$ end, referred to in genetic jargon as the upstream end and the downstream end, respectively. The first part of the upstream sequence is the promoter or regulatory sequence, and each gene has its own individual promoter (sometimes the word 'gene' includes the promoter, and in other terminology it does not). The promoter may be as long as or longer than the actual gene coding sequence. The latter sequence is also frequently interrupted by introns, which do not contribute to the final protein product when the gene is read. The bits that do contribute are called exons, so a gene is most frequently an interrupted DNA sequence.

In order to isolate genes, DNA is purified by a process of preferential solution, enzyme digestion of unwanted material, and centrifugation. Pulling out the desired sequence and separating it from the rest of the chromosomal DNA depends on preferential hybridization, often using analogous sequences from other organisms. In order to undertake transgenesis, genes are required in large numbers of copies (many millions) and this scale-up is known as cloning. Most commonly, genes are cloned by being placed inside the plasmids of a bacterium, the plasmids reintroduced into living bacteria, followed by growth of large numbers of the new gene-transformed bacteria. Finally, after growth of a large culture of such bacteria, the cells are harvested, the plasmids isolated, and the gene of interest recovered in bulk by preferential digestion with the so-called restriction enzymes. The end product of this process is a small volume of, say, 10 ml of dilute saline in which are dissolved many millions of copies of the desired DNA sequence.

Gene Introduction

Usually, the novel genes are introduced into the fertilized eggs of the chosen fish species, and one of the attractions of fish as a model system for transgenesis is that they lay large number of eggs. Often the unfertilized eggs and milt (sperm) are artificially stripped from captive fish and then mixed in a dish to allow fertilization and provide a batch of newly fertilized eggs for the gene introduction. Sometimes unfertilized eggs or young embryos have been employed for attempted transgenesis, but much more frequently fertilized eggs are used.

Figure 1 (a) Gene and its structure within a DNA double helix. (b) The linear structure of a gene and its promoter, showing the intron and exon sequences. The whole sequence is initially transcribed into the high-molecular-weight RNA transcript, but this molecule is then modified by the splicing out of the introns, so that the resultant messenger RNA contains only the exon sequences spliced together. The message is therefore, in almost all cases, much shorter than the gene. Partly redrawn from figures by Alberts B, *et al*. (2002) *Molecular Biology of the Cell*. New York: Garland Science.

In the case of the pioneering work with mice, the novel gene copies were introduced by injection into the egg cell nucleus. However, in fish eggs the nucleus is too small and invisible even when using a dissecting microscope, so the gene copies are introduced into the cytoplasm, in the hope that some will find their way to the chromosomes, perhaps during mitosis, and then be incorporated. Since this is a very low frequency event, very large numbers of gene copies, often in excess of 1 million per egg, have to be introduced to give any chance of successful integration.

Sometimes the eggs are placed in a dilute saline solution along with the gene copies and a powerful electric current used to drive some of the copies into the eggs. This is called electroporation. More commonly, the genes in solution are injected into the eggs using fine glass needles and a dissecting microscope. A mechanical machine known as a gene pulser can be used to ensure the appropriate volume and pressure. In some eggs, such as those of carp and zebrafish, the egg chorion is sufficiently soft to allow easy penetration by a fine glass needle, but with eggs of fish species such as salmon, trout, and tilapia, the chorion is very tough and the needle can only be inserted into the egg via the micropyle, which is the narrow tube in the chorion that permits sperm entry. Large numbers of eggs must be injected to allow recovery of some in which chromosome integration has followed on from gene injection.

Gene Incorporation

Since gene translocation (movement of a length of coding DNA from one chromosomal site to another) is a known natural phenomenon in genetics, it is evident that at least theoretically, once inside a cell nucleus, DNA can integrate into a chromosome and so come to permanently occupy a new locus. Following the introduction of many thousands of copies of the transgene, there is the low but significant possibility that one or more of these copies will be integrated, and indeed this is the finding in all transgenic fish programs. A range of methods have been tried to increase the probability of incorporation, and perhaps the most successful of these has proved to be the co-injection, along with the transgene, of molecules of meganuclease. Meganucleases are a kind of restriction endonuclease enzyme which has a long recognition sequence. The trick here is to flank the transgene with two meganuclease recognition sites and co-inject together with molecules of meganucleases. This has led to highly efficient transgenesis in zebrafish with improved integration frequencies and germ line transmission. Although in the fish transgenesis so far practiced, the transgene integration sites are randomly distributed throughout the chromosomes, it could be that the future site-specific integration could be achieved with the clever manipulation of meganucleases.

It is worth stressing that the use of the meganuclease technique, with its increased frequency of transgene integration, also goes some way to offset another problem with fish transgenesis, namely mosaic expression following integration of the transgene in the first-generation fish (and, as a result, frequent failure of such fish to pass the transgene on to progeny because the gonads are not one of the tissues carrying the transgene construct). Such mosaic expression clearly results from late incorporation of a transgene copy after some rounds of embryonic cell division, so that only one cell out of say 8 or 16 cells actually comes to be involved in an integration event.

Another technique now important in achieving good integration frequencies with fish transgenesis is the use of transposable elements. A number of such elements have been tried, and one notable example is the Sleeping Beauty transposon, so called because it was reactivated by targeted mutagenesis of an ancient inactive transposable element recovered from salmon. Here the procedure is to place the transgene construct within the transposon sequence prior to injection. High rates of transgene integration in fish have been achieved in this way. It is worth emphasizing that damage to host genes by transgene integration (so-called insertional mutagenesis) into chromosomes is rare in fish. This is probably explained by the large amount of essentially redundant DNA found in vertebrate genomes, so most often transgenes are integrated in nonfunctional noncoding DNA sequences.

Gene expression

When transgenesis was first envisaged as an experimental technique, there were substantial fears that transgenes would fail to express due to selective DNA methylation or some other gene-silencing mechanism. Fortunately, this has proved to be a rare phenomenon. Gene expression is of course mainly determined by the promoter driving the gene of interest within the construct, and often in the early stages of an experimental program in transgenesis, ubiquitously expressing promoters are employed to bring about gene expression at all times in all tissues. Once expression has been achieved, further work with tissue-specific promoter sequences can be attempted.

It should not be assumed that transgene expression is always indicative of chromosomal integration of the construct. Indeed, the so-called transient expression of unintegrated copies is frequently observed, but this will not survive long once embryonic formation is under way. A device that is often used in a transgenesis program is the employment of reporter sequences. These are genes such as green or red fluorescent protein (GFP or RFP) genes recovered from jellyfish, or the luciferase gene recovered from a firefly, or the beta

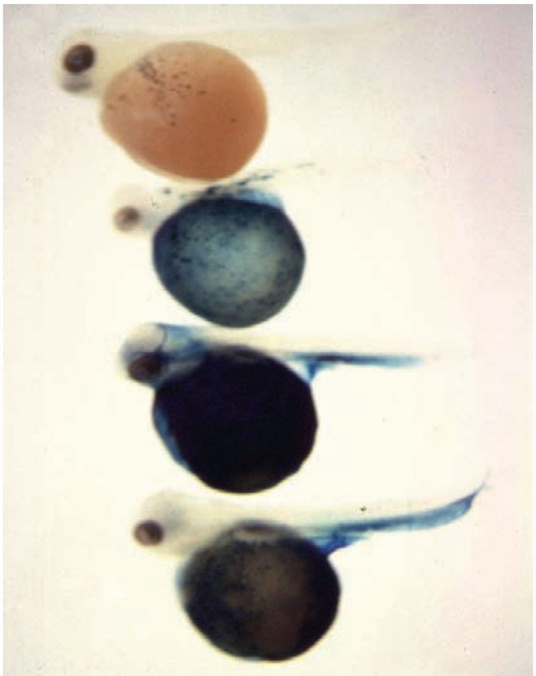

Figure 2 A series of newly hatched tilapia embryos following egg injection with a lac Z reporter gene and subsequent treatment to reveal the color. The uppermost embryo is nontransgenic and the lower three show different degrees of expression in the skeletal muscle. The yolk sacs are also stained. This is not in the yolk itself but in the thin layer of cells covering the yolk. Figure from Maclean laboratory.

galactosidase enzyme gene derived from the bacterium *Escherichia coli.* All of these genes, when coupled with an appropriate promoter, provide a visible color within the cells of the recipient organism (see **Figure 2**). The color may be directly visible, or made visible by the addition of the substrate luciferin in the case of luciferin, or of a blue color from beta galactosidase when X gal staining is carried out. It is understandable, therefore, that constructs made up of chosen promoters, driving both reporter genes and other genes of interest in tandem, are often employed in establishing the early stages of a transgenesis program with fish.

There are few experiences as exciting and rewarding as visualizing the tissue-specific expression of a reporter gene within the cells of a young fish following the demanding and labor-intensive process of injecting large numbers of fish eggs.

As mentioned earlier, expression of a gene is substantially a function of the promoter with which it is teamed, and promoters can be quite complex sequences, containing negative as well as positive transcription enhancers. Thus, designing a promoter to give the desired level and tissue specificity of expression is a highly important aspect of achieving a satisfactory expression profile within the transgenic fish.

Gene Transmission

Most frequently, the Holy Grail of any transgenesis program is to achieve germ line transmission of the transgene construct to progeny fish. Often this will have been previously attempted using a reporter gene construct to ensure that it is indeed feasible. Almost invariably, since transgene integration is a rare event, integration will have occurred into only one of a pair of chromosomes in the set, and so the original transgenic fish will be heterozygous for the transgenic sequence. Since transmission is mendelian, when the transgenic fish is crossed with a wild type, about half of the progeny will carry the transgene and they too will be heterozygous. Only by further crossing of two of the positive progenies will homozygous transgenics be obtained, and these will be approximately 25% of the resulting progeny, with another 25% wild type and 50% heterozygous transgenics.

Occasionally, odd numbers of positive progeny will be found, resulting from two or more separate transgene integrations in the same chromosome set. Heterozygous progeny should of course be nonmosaic, so that every cell and tissue should carry the same single incorporated transgene in one chromosome of the set.

If the transgene is driven by a ubiquitous promoter, then expression should be evident in all tissues of the progeny fish, or, if the promoter is specific in its expression to say, liver, then only liver cells will express in the progeny. Both situations are illustrated in **Figure 3**.

There is often interest in the long-term persistence of the transgene construct. There are examples cited in the literature of transgenes being lost from the chromosomes at some time after its initial germ line transmission. This presumably may result from some failure at mitosis or meiosis, but this seems to be very rare. More commonly, the explanation for subsequent transgene loss is that the transgene was never integrated in the first place but was transmitted and expressed as a nonintegrated nuclear episome. Examples of such entities certainly exist in the literature.

The Usefulness of Transgenic Fish

There is a wide spectrum of different applications through which transgenic fish have already proved to be useful and also offer great promise for the future. They include studies on gene regulation and exploitation of transgenes as signals of gene expression in model fish systems. Second, strains of GM fish can be produced which promise to offer aquaculture strains that improve on those currently used. Third, transgenic fish can be designed to allow environmental monitoring of pollutants. Lastly, there is promise that transgenic fish can be used as biofactory systems for the production of valuable

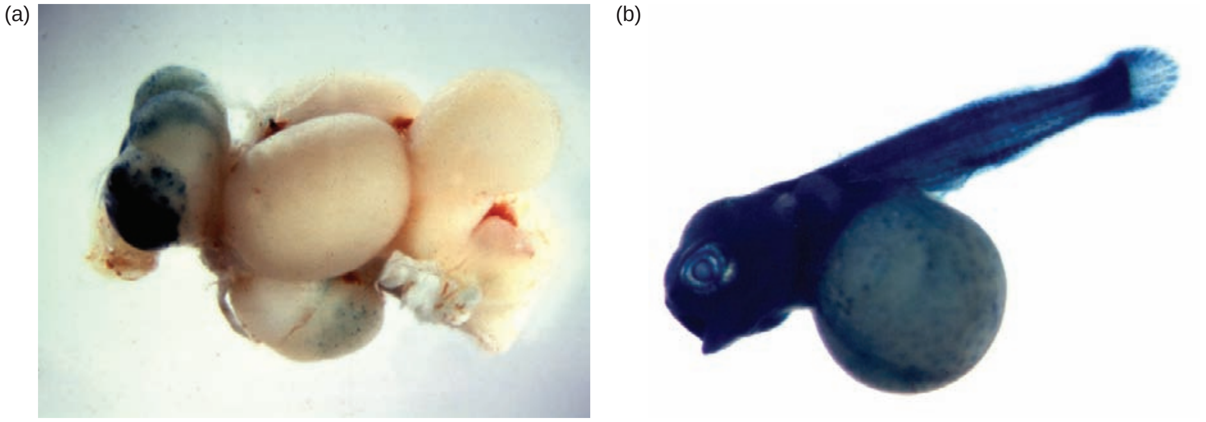

Figure 3 (a) The brain of an adult transgenic tilapia fish dissected out and treated to show localized tissue-specific expression of the lac Z reporter gene in the optic lobes. (b) A tilapia embryo transgenic for carp beta actin promoter spliced to the lac Z gene, showing all over-expression of this ubiquitously expressing promoter. Treated to show lac Z expression. (a, b) Figure from Maclean laboratory.

pharmaceuticals or of cells or tissues which offer benefits to human medicine.

Studies on gene regulation with transgenic fish

These studies have mainly been carried out with small model fish species such as zebrafish (*D. rerio*) or medaka (*O. latipes*), and sometimes with larger species such as goldfish (*Carassius aureus*) or tilapia (*Oreochromis niloticus*) as well. Transgenesis is an attractive methodology because reporter genes can be used to indicate levels of gene expression in particular tissues, and, when combined with the comparative transparency of the embryos of these fish species, to demonstrate in which cells and tissues particular genes are active. They can even be used to track cell movement *in vivo*.

A good example is provided by the splicing of a reporter gene for fluorescent protein to a promoter for a gene called vasa, which is only ever expressed in the early germ cells. The germ cells then light up in the positive fish, allowing them to be counted and their path of travel from the site of origin to the embryonic gonad displayed (see **Figure 4**). Labeling of specific cells within transgenic embryos has also allowed other specific cell migrations to be charted.

The cellular specificities of particular promoters can also be determined in this way, as well as the fine-scale analysis of the structure of particular promoter sequences, so that positive upregulators or downregulators (suppressors) of specific gene expression can be discovered.

Much of the attraction of GM mice for researchers follows from the ability to knock out expression of a single gene and then study the phenotype of the transgenic mice carrying the knock-out. In this way, for example, it has been shown that mice in which the PrP gene that codes for prion protein (as in mad cow disease) is knocked out are apparently normal. So here is a gene which appears to have no function in normal humans, but when its protein product is misfolded it can cause serious disease. Although this gene knock-out technology is not effective in GM fish, an alternative methodology involving the use of specific oligonucleotide morpholinos permits short-term gene knock-out and therefore studies on early expression of important developmental genes.

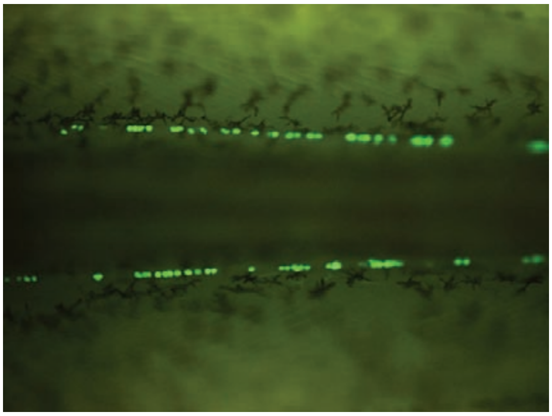

Figure 4 Primordial germ cells of rainbow trout labeled with a green fluorescent reporter gene driven by the vasa promoter from the same species. Vasa expression is specific to these cells. Photo kindly provided by Prof. Yoshizaki. From Takeuchi Y, Yoshizaki G, Kobayashi T, and Takeuchi T (2002) Mass isolation of primordial germ cells from transgenic rainbow trout carrying the green fluorescent protein gene driven by the *vasa* gene promoter. *Biology of Reproduction* 67: 1087–1092.

A further way in which transgenic model fish have contributed to our knowledge of gene regulation follows from the exploitation of particular hybrid crosses between swordtail species (*Xiphophorus*) fish. Some of these hybrids suffer from a form of pigmented melanoma. The transgenic regulation of tumor suppressor genes in these fish which grow melanomas has revealed valuable information about cancer activation and suppression in humans (see **Figure 5**).

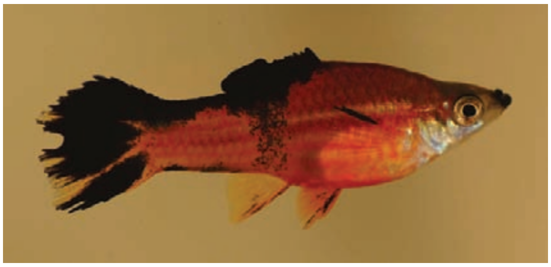

Figure 5 Spontaneous melanoma formation in a crossbred *Xiphophorus* fish. The expression and suppression of tumors in these fish have been manipulated transgenically in Prof. Manfred Schartl's lab in Germany to reveal the genes involved in this cancerous tumor formation. This has proved informative for the understanding of tumor formation in humans. Photo kindly provided by Prof. Manfred Schartl. From Meierjohann S and Schartl M (2006) From Mendelian to molecular genetics: The *Xiphophorus* melanoma model. *Trends in Genetics* 22(12): 654–661.

Development of GM fish offering potential benefits to aquaculture

With the decline of ocean fish stocks as a result of extensive over-fishing, aquaculture has an ever-increasing role in the production of animal protein for human food. Although aquaculture has long been critically important in the economies of countries such as Thailand and China, in recent years the aquaculture of rainbow trout (*O. mykiss*), various salmon species, and of Atlantic cod (*Gadus morhua*) has become very important in countries such as Chile, Norway, and North America.

The parameters which have been modified to date in appropriate species of GM fish include growth enhancement, freeze resistance and cold tolerance, disease resistance, and sterility.

Growth-enhanced transgenic mice were famously produced in the USA in 1982, and since then it became an ambition of fish biologists to produce similar strains of growth enhanced GM fish. As shown in **Figure 6**, fast-growing strains of various salmon species, tilapia, carp, and mud loach have been successfully produced. Some of these strains appear to be commercially attractive, especially since no other undesirable traits are apparent in such fish. These fish can also be made sterile, sometimes reversibly. An additional transgenic modification with some of these fish is to produce them autotransgenically, meaning that the entire transgene sequence of promoter, structural gene, and downstream DNA sequence has been recovered from the same species as is now made transgenic, so such fish carry no novel DNA sequences, but have simply undergone a minor rearrangement of genes in their own genome. If autotransgenesis is coupled with reversible sterility in the future, it would surely offer fish which would be widely acceptable in aquaculture.

Another parameter of interest in fish for aquaculture is resistance to cold or freezing. The latter involves resistance to freezing in water which is below the freezing temperature of freshwater. Many species of Arctic fish such as winter flounder (*Pseudopleuronectes americanus*) carry specific genes which code for antifreeze protein. These small proteins are released into the blood and tissues of Arctic fishes, and prevent freezing of the fish. Genes for antifreeze protein have been recovered from such fish species and transferred and expressed in species such as Atlantic salmon (*Salmo salar*) to allow their aquaculture production in the Arctic. However, to date the synthesis of antifreeze protein by such transgenic fish is insufficient to render them truly freeze-resistant.

Cold tolerance to temperatures below 10 °C would be a considerable benefit to carp culture in China or tilapia culture in Israel, and there is certainly some possibility that cold-tolerant transgenic strains of such fish could be developed.

Development of transgenic fish which are resistant to common fish diseases such as furunculosis in salmon could also have great potential. While there is evidence

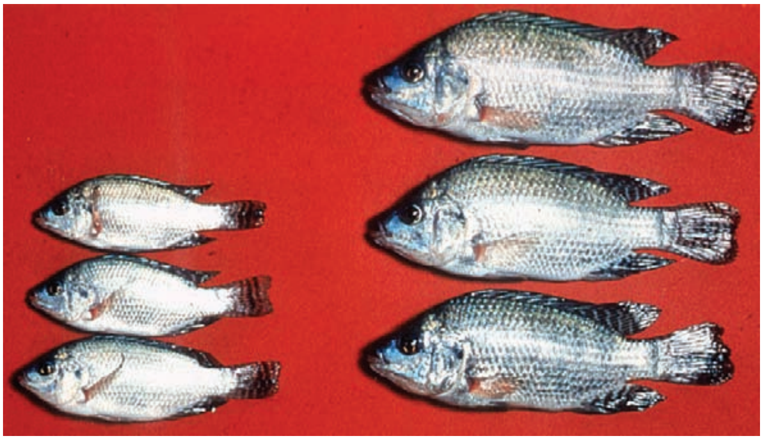

Figure 6 Growth-enhanced transgenic tilapia expressing a growth hormone transgene from a different fish species. Three control fish are on the left and three transgenically growth-enhanced fish are on the right. Figure from Maclean laboratory.

in the literature of the production of GM fish strains with improved levels of disease resistance, such work is still at a very early stage of development.

The last parameter to be considered as a potential benefit to aquaculture is sterility. Such a feature would prevent the spread of transgenes into wild fish stocks should transgenic fish escape. Nontransgenic sterility can be achieved in fish by triploid induction. In addition, the antagonization of some of the sex hormones such as gonadotropin-releasing hormone (GnRH) allows reversibly sterile strains of GM fish to be produced. Such fish would remain sterile unless the production of the GnRH antisense is negated by injection of GnRH at an early stage of development. There is some experimental evidence in tilapia that this research goal is indeed achievable.

Fish as Environmental Indicators

It is at least theoretically possible to design GM fish to act as indicators of environmental pollution. The rationale is to combine a promoter for a gene such as metallothionein, which is activated by heavy metals such as cadmium or copper, to a reporter gene, for example, GFP. The fish would then glow green if the water contained a high but nonlethal level of a heavy metal. This has indeed been attempted but the evidence for success is still somewhat incomplete.

GM Fish as Biofactories

Since fish are comparatively cheap to produce and easy to keep, it is clear that they may make attractive systems for the production of pharmaceuticals. Rival methodologies exist for yeast cells, GM plants, GM chickens (for production of egg protein), and GM mammals (for production of milk).

The system which has been tried in fish in Southampton is to produce transgenic tilapia (*O. niloticus*) capable of expressing a human blood clotting factor, factor VII. This factor is not important in hemophilia but is important in the control of internal bleeding such as occurs following gunshot injury, or from rupture of spleen or liver following car accidents. Currently, human factor VII is produced in human tissue culture cells and is very expensive. The strategy employed with tilapia was to render the fish transgenic for a construct consisting of a liver specific promoter (vitellogenin) spliced to a copy of the gene from human factor VII. The tilapia fish did indeed synthesize human factor VII capable of clotting human cells, but the research effort stopped before the amount of factor VII produced by the fish was of truly commercial significance.

Another application with medical potential has been followed up in Toronto, Canada. This is to humanize the tilapia copy of the insulin gene so that tilapia produce human insulin, with a view to making tilapia liver tissue from such fish available for transplant to humans suffering from advanced insulin-dependent diabetes.

Colorful Fish for the Pet Trade

A further use for GM fish has been found with glowfish, transgenic zebrafish which express GFP or RFP (from jellyfish) in their muscle. This has no undesirable effect on the fish but endows them with a novel color property. Such fish have been authorized for sale in the pet trade in the USA (see **Figure 7**).

Problems with Transgenic Fish

GM animals and plants have aroused considerable public anxiety, especially where they might be used for food production. Such anxiety is currently maximal in

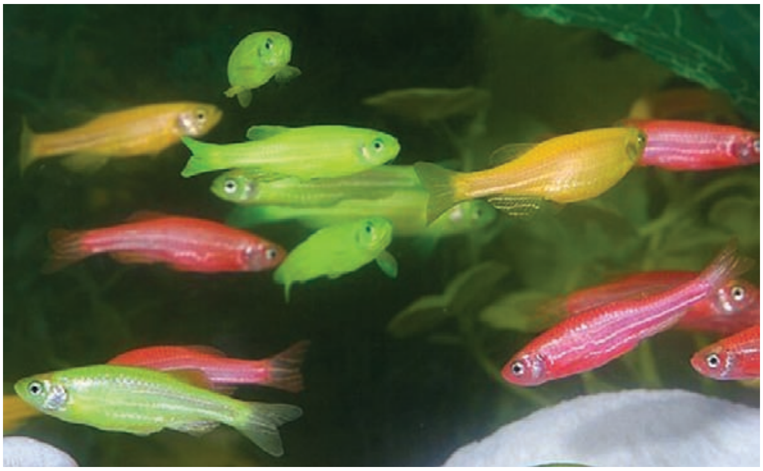

Figure 7 Glowfish which are a line of transgenic zebrafish offered for sale as pets in the USA. Reproduced from www.glofish.com.

Europe and fairly minimal in the USA. GM fish present some particular problems because of their mobility and the comparative difficulty of ensuring physical containment at all times. There is no doubt that GM organisms could be produced by accident or intention which would prove hazardous to health if eaten, just as some non-GM organisms are poisonous. However, provided the design of transgenic organisms is wisely planned, no significant health hazards need arise. Certainly, there is no particular property acquired by a promoter or coding sequence when used as a transgene which would render it more hazardous than the normal sequence in the nontransgenic organism.

The containment of transgenic fish can be achieved either physically, for example, by their culture in a land-locked lake or secure aquaculture facility, or by ensuring that they are sterile and so unable to mate with wild individuals should they escape. Where it has been proposed to exploit transgenic fish in commercial aquaculture, as for example with growth-enhanced GM Atlantic salmon in North America, it has been proposed to use all-female triploid fish which are indeed sterile. It is an interesting question to determine how dangerous an accidental escape of GM fish might be if they were, for example, growth enhanced. Present genetic evidence favors the view that such fish are significantly less fit than normal wild fish, and would eventually die out through disease or predation. However, at the present time, it is difficult to be 100% sure that extinction would always follow from accidental escape, and it is clearly better to ensure containment at all times.

Concerns have also been raised about the hazards of transgenesis induction, in terms of unexpected side effects of the transgenesis process. As with normal plant and animal breeding, new transgenic strains should obviously be rigorously tested before being used for commercial production and especially if destined for medical use or for food. Theoretical possibilities exist for nontarget genes being accidentally inactivated through transgene insertion, or through transgenes affecting the expression of adjacent gene sequences following integration. There is even a theoretical possibility of the accidental activation of viral or proto-oncogene sequences following transgenesis. Such possibilities seem to be more theoretical than real, and so far such problems have not been encountered in practice.

Chromosome manipulation in fish

Chromosome manipulation is usually taken to mean ploidy manipulation, most frequently triploidy. Triploid fish can offer certain advantages. They are normally sterile, especially when female, and the lack of gonadal development may lead to increased growth as compared to wild-type diploids when the fish would normally be sexually mature. However, most frequently triploids are produced to ensure sterility when such fish are used for stocking. To understand how triploid fish are produced, it is necessary to know something about normal gametogenesis in fish. The fish egg results from two rounds of division of a primary oocyte which carries four copies of each chromosome, that is, it is tetraploid. In two rounds of division the primary oocyte produces first a diploid cell plus a tiny polar body carrying the other chromosome set, and then in a further division a haploid egg cell is produced and a second tiny polar body is expelled. If the oocytes are recovered from a fish and treated to either heat-shock or pressure-shock, the elimination of the second polar body may be prevented, leading to a diploid egg. On fertilization with normal haploid sperm, such an egg develops into a triploid embryo and organism.

Although both male and female triploid fish are commonly sterile, occasionally some triploid males may secrete small amounts of viable sperm. For this reason all-female triploid fish are favored.

The production of all-female triploids is ensured by the use of sperm from female fish which have been emasculated by injection with male sex hormone. Such females go on to develop testes and secrete sperm, but it is all genetically female-determining sperm, since the male is the heterogametic sex. Thus, all fish resulting from the fertilization of diploid eggs with female-determining sperm are all-female triploid fish, and these can be guaranteed to be sterile.

The physiology of triploid fish is described in **Cellular, Molecular, Genomics, and Biomedical Approaches**: Physiology of Triploid Fish.

Applications of triploidy

Triploid fish are now widely favored in the management of wild trout rivers for stocking purposes. For example, the province of British Columbia, Canada, has a very large, province-wide stocking program for its lakes that had been depleted of wild stocks by overfishing. These fish do not divert energy into sexual development or secondary sexual characteristics. Furthermore, the techniques of transgenesis and triploid induction are sometimes combined in fish to produce lines of sterile GM fish which would not pose an environmental risk to interbreeding with any wild stock. Sterile triploids are also of considerable interest as mentioned previously, when GM fish are likely to be used in commercial situations where accidental escape could not always be avoided.

Although semantically transgenesis can be viewed as a chromosome manipulation, in most countries the two procedures are viewed as distinct, the term gene manipulation being reserved for cases where the novel genes are artificially manipulated. However, it is well to be aware that in some countries such as Germany chromosome manipulation as in triploid induction is categorized as GM and is covered by the same legislation.

Gynogenesis and androgenesis

Triploidy is not the only interesting aspect of chromosome manipulation in fish. Both gynogenesis (all maternal inheritance) and androgenesis (all paternal inheritance) can be used to produce inbred clonal lines of fish.

Diploid gynogenetic fish can be generated by blocking first cleavage during oocyte maturation, or by blocking the extrusion of the second polar body. Often such eggs are fertilized with irradiated sperm to ensure further embryo development without any male genetic contribution.

Diploid androgenic fish can be produced by irradiating eggs then fertilizing with normal sperm, and then allowing doubling of the paternal genome by blocking the first cleavage, resulting in a doubling of the sperm donated genome.

Although such clonal lines of fish are normally less attractive for aquaculture and more prone to disease and reduced growth, they are of considerable interest to scientists studying fish immunology, since clonal fish may accept tissue grafts such as scales from one another without rejection. The Laboratory of Fisheries at Wageningen Agricultural University in the Netherlands has used such gynogenetic and androgenetic homozygous clones of fish for studies on fish tissue transplantation.

Glossary

Aneuploid Having any number of chromosomes other than an exact multiple of one complete chromosome set.
Chromosome set A single complete complement of chromosomes.
Dioecious Having separate sexes.
Diploid Having two complete chromosome sets.
Gene dosage The number of copies of a given gene.
Heterozygous Having variability in alleles for a given gene or genes.
Hypotonic Having a lower salt concentration.
Mean erythrocyte hemoglobin concentration The mean concentration of hemoglobin per erythrocyte.
Parthenogenesis Development in the absence of a paternal genome.
Polyploid Having more than two complete chromosome sets.
Sterile Unable to produce viable offspring.
Tetraploid Having four complete chromosome sets.
Triploid Having three complete chromosome sets.

Introduction

Most fish are diploids, with their genomes comprised of two sets of homologous chromosomes. Polyploid fish have a greater number of complete chromosome sets, with the most common being triploids (three sets) and tetraploids (four sets). Although polyploidy is more common in plants than in animals, tetraploidy has played an important role in vertebrate evolution as a mechanism for providing redundant genes that can mutate with less likelihood of being lethal. However, additional sets of chromosomes require a larger nucleus to house them, and this often results in a larger cell size as well. Adaptive benefits of polyploidy could potentially be counterbalanced by physiological constraints arising at the organismal level from this increased cell size. The fact that numerous anscestral polyploid lineages have survived their diploid progenitors indicates that the genetic benefits of polyploidy can outweigh any physiological consequences.

There are many examples of both naturally occurring and artificially induced triploidy in fishes. Naturally occurring triploids fall into two categories: occasional spontaneous triploid individuals within dioecious diploid species and self-sustaining triploid populations with atypical modes of reproduction. Fish of the former category have been reported in a diversity of species, from sharks to teleosts. Fish of the latter category occur as female hybrids between two closely related species and typically reproduce by parthenogenesis. Triploidy has been induced in many species of fish, generally with the aim of producing sterile populations for aquaculture or fisheries management. This is most commonly achieved through thermal or hydrostatic pressure treatment of eggs (a shock) shortly after fertilization, thereby interfering with the completion of meiotic reduction of the maternal genome within the oocyte (**see also Cellular, Molecular, Genomics, and Biomedical Approaches:** Transgenesis and Chromosome Manipulation in Fish).

Triploids can potentially differ from conspecific diploids in a number of fundamental ways. Those that arise spontaneously or are induced in species that normally exist as dioecious diploids are more heterozygous, have unbalanced gene dosage, and are sterile. All triploids, independent of their origin, also have larger cell nuclei to accommodate their larger genomes, resulting in increased cell volume in many cell types. Increased cell volume in triploids is balanced by reduced cell numbers (to maintain normal organ and body size), reduced cellular and nuclear surface area per unit volume, and increased intracellular diffusion distances.

The genetic consequences of triploidy (heterozygosity and gene dosage) are not considered in this article. Rather, the focus is on the physiological effects of triploidy on fish biology, which are ultimately linked to sterility and increased cell volume.

Reproductive Physiology

Although there are a few examples of self-sustaining triploid populations of fish that have arisen through hybridization events, these are rare and exist as female clones that require males from one of the progenitor species to activate development of their eggs. Aside from these exceptions, triploids are reproductively sterile. This is a direct consequence of having an odd number of chromosome sets. The unpaired chromosome set leads to a failure of the normal pairing and crossing-over of homologous chromosomes that occurs during meiosis I.

At the time when diploid females are sexually mature, triploid ovaries are largely devoid of vitellogenic oocytes (**Figure 1**). The small numbers of oocytes that do occasionally become vitellogenic in triploids are rarely – if ever – ovulated. Steroid biosynthesis is greatly diminished or absent in triploid ovaries due to their small number of developed follicles. As a result, triploid females retain juvenile endocrine profiles throughout their lives, whether at the level of the ovary (steroids), liver (vitellogenin), pituitary (gonadotropins) or hypothalamus (gonadotropin releasing hormone), and they do not develop secondary sexual characteristics (**Figure 2**). All of these endocrine systems are fully competent and respond appropriately to exogenous steroid treatment to replace the absent endogenous steroids (**see also Hormonal Control of Reproduction and Growth:** Endocrine Regulation of Fish Reproduction).

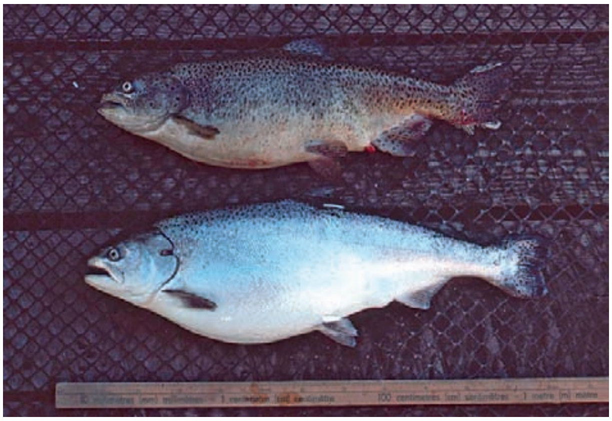

Figure 2 Secondary sexual characteristics in a sexually mature diploid female chinook salmon, *Oncorhynchus tshawytscha* (top), compared to a sibling triploid female that has retained the juvenile appearance (bottom). Note the darker coloration and protruding vent in the diploid. Photo: Tillmann Benfey, University of New Brunswick.

The situation for triploid males is quite different: they often produce functional, post-meiotic spermatozoa, although in much smaller numbers than diploids. These cells are larger than the haploid spermatozoa produced by diploid males, and flow-cytometric measurement of DNA content shows them to be aneuploid with a distribution of genomic DNA content that peaks midway between haploid and diploid. Triploid males appear outwardly to mature normally. They develop relatively large testes (**Figure 3**) through the pre-meiotic proliferation of spermatogonia, and their testes are fully invested with functional steroidogenic cells. As a result, triploid males have reproductive endocrine profiles identical to those of

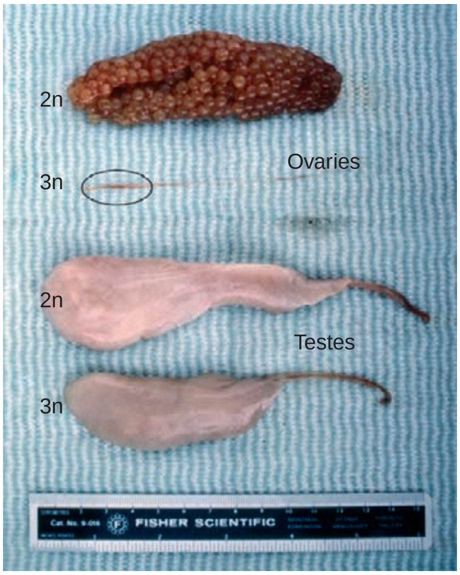

Figure 3 Gonadal development in sibling diploid (2n) and triploid (3n) pink salmon, *O. gorbuscha*. Photo: Tillmann Benfey, University of New Brunswick.

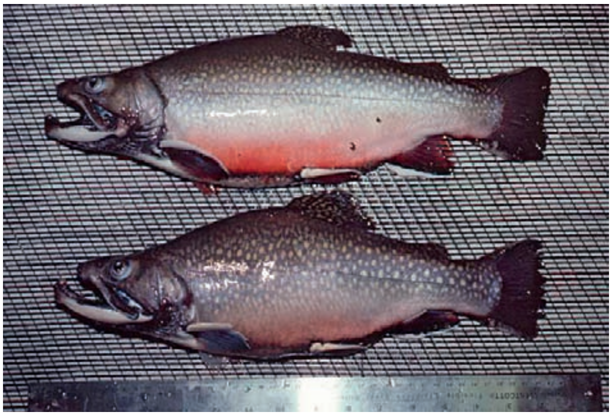

Figure 4 Secondary sexual characteristics in a sexually mature diploid male brook charr, *Salvelinus fontinalis* (top) compared to a sibling triploid male (bottom). diploids, in spite of producing greatly reduced numbers of spermatozoa. They also develop typical secondary sexual characteristics (**Figure 4**), and they have normal rates of precocious maturation and spawning behavior. Their spermatozoa are able to fertilize eggs, but the resultant offspring are aneuploid and die early in development. Some studies have found sperm motility to be the same for triploid and diploid males, but others have found the former to have reduced sperm motility (**see also The Reproductive Organs and Processes:** Anatomy and Histology of Fish Testis and Vitellogenesis in Fishes).

Hematology, Gas Transport, and Cardiovascular Physiology

The effect of triploidy on cell size is clearly demonstrated for the nucleated erythrocytes of fish, which are approximately 40% larger in volume than those of diploids (**Figure 5**). This increase in cell size is so extensively documented that it is often the sole criterion used to confirm ploidy level in fish. There tends to be a proportionately greater increase in cell length than in cell width or height, with the result that triploid erythrocytes not only appear larger but also more elongated than diploid erythrocytes when viewed in blood smears. Although not well quantified, any such increase in cell size necessarily reduces the cellular surface area to volume ratio.

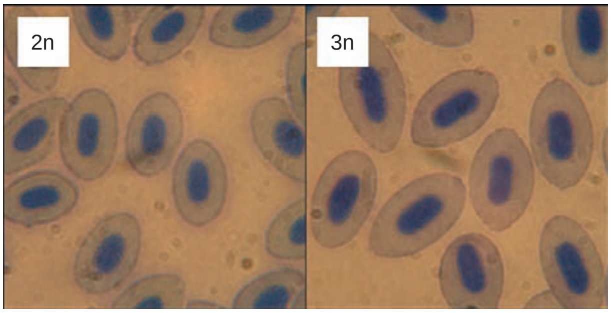

Figure 5 Diploid (2n) and triploid (3n) Atlantic salmon, *Salmo salar*, erythrocytes at identical magnification. Photo: Tillmann Benfey, University of New Brunswick.

Increased erythrocyte volume is balanced by reduced cell numbers, such that there is no effect of triploidy on the proportion of the blood volume occupied by blood cells (i.e., hematocrit). Most studies have also shown equivalent blood hemoglobin concentrations in diploids and triploids. Mean erythrocyte hemoglobin concentration (**see also Blood:** Cellular Composition of the Blood) is similar in diploids and triploids, but the absolute amount of hemoglobin per cell is higher in triploids because of their larger cell volume.

Based solely on hemoglobin concentrations, the oxygen-carrying capacity of individual erythrocytes should be higher for triploids than for diploids, while blood oxygen-carrying capacity should be the same. However, the percentage oxygen saturation of hemoglobin in triploid chinook salmon is about 75% of diploid values over a range of swimming speeds, that is, their hemoglobin is less fully saturated (**see also Transport and Exchange of Respiratory Gases in the Blood:** Hemoglobin). Consequently, they characteristically have lower arterial blood oxygen content (about 70% of diploid values). The cause of this is unclear; the limited data available for chinook and Atlantic salmon indicate that it is not likely due to any significant effect of triploidy on the principal factors controlling hemoglobin's binding affinity for oxygen, such as blood pH or erythrocyte organic phosphate concentration. What has not been adequately considered (or tested) is whether the reduced surface area of erythrocytes (relative to their volume) limits the rate at which oxygen enters and exits the cells. However, surface area does not appear to limit carbon dioxide exchange across the erythrocyte cell membrane in triploids. Another possibility is that gill vascular dimensions and anatomy (**see also Design and Physiology of Arteries and Veins:** Anatomical Pathways and Patterns and Branchial Anatomy) are altered in triploids.

Capillary diameter must be carefully regulated to minimize the distance for gas exchange between erythrocytes (**see also Design and Physiology of Capillaries and Secondary Circulation:** Capillaries, Capillarity, and Angiogenesis) and the surrounding tissues without causing excessive resistance to blood flow. This is achieved through erythrocyte deformation as they pass through capillaries that typically are narrower than erythrocyte diameter. It is not known whether capillary diameter is increased in triploids to accommodate their larger cells or whether triploid erythrocytes undergo greater deformation as they pass through the capillaries. Greater deformation and/or increased pressure on the cells as they pass through the microvasculature could affect their structural integrity. A single *in vitro* study of blood viscosity in triploids concluded that increased erythrocyte size does not increase vascular resistance. Several studies have shown that triploid erythrocytes are more resistant than diploid cells to rupture (hemolysis) when exposed to hypotonic solutions (**Figure 6**), suggesting that they differ in cell membrane composition and/or cytoskeletal structure. This would be an interesting compensatory mechanism to protect erythrocytes from size-related damage resulting from their passage through the microvasculature, and warrants further study. Perhaps unrelated, but also needing further research, is the origin and physiological implications of characteristic erythrocyte nuclear and cellular abnormalities routinely observed in triploid fish (**Figure 7**).

Several studies have shown triploids to be less able to survive chronic exposure to what would be considered high, but sublethal, temperatures for diploids. Triploid trout reared at elevated temperature have exceptionally high heart rates, and it has been suggested that mortalities at such temperatures may be due to myocardial infarctions or aneurysms. However, *in vivo* and *in vitro* studies of cardiac performance have concluded that it is not remarkably affected by triploidy. These studies have not included diploid controls, and further research is needed on the effects of triploidy on cardiac function and output. A single study, using brook charr at embryo-larval stages, found no effect of triploidy on heart rate or cardiac output.

Respiration and Metabolism

Effective respiration in fish requires an efficient mechanism for moving water across the gills. Triploid salmonids and Atlantic cod occasionally have lower jaw deformities that prevent full closure of the mouth (**Figure 8**). Triploids also sometimes have a higher incidence of shortened opercula that are missing the skin flap used to seal the exits from the opercular cavities. The efficiency of the buccal-opercular pumping system used for gill irrigation depends on the ability to seal all compartments within the system, suggesting that under some

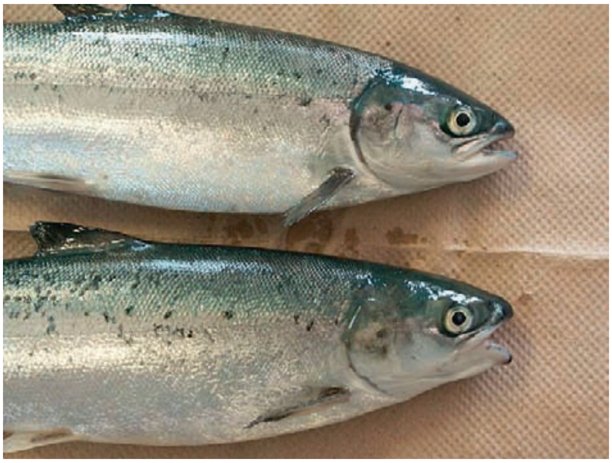

Figure 8 Diploid (top) and triploid (bottom) Atlantic salmon post-smolts showing characteristic lower jaw deformity more frequently observed in the triploid. Photo: Saranyan Pillai, University of New Brunswick.

circumstances (lower jaw deformity and/or shortened opercula), triploids may have reduced respiratory efficiency. Although there are no direct data on the efficiency of triploid respiratory systems, triploid Atlantic salmon with lower jaw deformities do less well in aerobic swimming tests than triploids and diploids lacking this deformity. Triploid brook charr have also been shown to have lower oxygen consumption rates than diploids at equivalent gill irrigation frequencies, but this was independent of their opercular condition and did not consider any differences in irrigation volume.

Gill anatomy (**see also Design and Physiology of Arteries and Veins:** Branchial Anatomy) can also be affected by triploidy. For instance, zones of missing filaments have been observed on the gill arches of triploid Atlantic salmon and they also have a lower total macroscopic gill surface area (**see also Ventilation and Animal Respiration:** Gill Respiratory Morphometrics) compared with diploids. Although there is no evidence of gill filament deformities in triploid tench (*Tinca tinca*), their gill secondary lamellae are longer and thinner than those of diploids, and the lamellar diffusion distance for respiratory gas exchange is approximately 30% shorter. This closer proximity of water and blood flow through the gills of triploids suggests some level of anatomical compensation, although there have been no studies on lamellar blood perfusion in triploids of any species.

Oxygen consumption rates are largely unaffected in triploids under a variety of test conditions. Numerous studies have shown that triploidy does not affect critical swimming speed (U_{crit}, a common proxy for aerobic capacity). However, triploids may accrue a larger oxygen debt during such swim tests, as suggested by the lower arterial blood oxygen content and hemoglobin–oxygen saturation noted above as well as higher post-exercise oxygen consumption rates noted in some (but not all) studies. Compared to diploids, triploid Atlantic salmon have reduced endurance when forced to swim at speeds above their maximum sustainable swimming speed (**see also Swimming and Other Activities:** Applied Aspects of Fish Swimming Performance), suggesting reduced anaerobic capacity. However, the data on blood and muscle levels of anaerobic metabolites after anaerobic exercise are equivocal as to whether there is a ploidy effect.

Stress Response and Environmental Tolerances

Triploid salmonids exhibit a typical physiological stress response when exposed to common acute stressors encountered in aquaculture, such as chasing, confinement, transportation, or seawater transfer. The peak levels and time course of recovery of plasma cortisol, glucose and lactate following exposure to such stressors are the same for both ploidies. However, triploids often do not survive as well as diploids under conditions of chronic stress brought about by typical aquaculture conditions. The two environmental stressors that have been examined in some detail in terms of physiological responses by triploids are temperature and salinity.

The critical thermal maximum (**see also Temperature:** Measures of Thermal Tolerance), which is the temperature at which fish lose their ability to maintain equilibrium and turn belly up when exposed to rapid temperature increases, is the same for triploids and diploids. The chronic lethal maximum, which is estimated using slower rates of temperature increase to provide some opportunity for thermal acclimation, is also unaffected by ploidy. However, triploids have markedly higher mortality rates than diploids when first acclimated to sublethally high temperatures and then exposed to stressors such as increased salinity or exhaustive exercise. The specific cause of mortality under such conditions is not known, but triploids have been shown to have a lower thermal optimum than diploids (based on the relationship between acclimation temperature and routine metabolic rate).

Physiological adaptation to the marine environment is an energetically demanding phase of the natural life history of salmonid fishes that can be associated with high mortality rates in aquaculture. Independent studies with a number of salmonid species have shown that triploids do not differ from diploids in their abilities to osmoregulate after transfer to seawater (**see also Osmotic, Ionic and Nitrogenous-Waste Balance:** Osmoregulation in Fishes: An Introduction), as evidenced by their similar plasma osmolalities and ion concentrations and gill Na^+/K^+-ATPase activities post-transfer. Interestingly, triploid chinook salmon smolts have been shown to have, on average, lower gill Na^+/K^+-ATPase activity prior to saltwater transfer (during the pre-adaptation stage), but this was not the case for non-smolting rainbow trout (*O. mykiss*). Plasma IGF-I levels, which are associated with osmoregulatory ability, do not differ between triploids and diploids.

Immunology and Disease Resistance

Just as for erythrocytes, triploid leukocyte size is increased and numbers reduced compared to diploids. Differential cell counts, used to estimate relative abundances of the different types of leukocytes, are generally the same for triploids and diploids. Respiratory burst and phagocytic activities are higher for triploid leukocytes due to their larger size, but when expressed per unit blood volume, there is no effect of triploidy. The balance between cell size and numbers also results in there being no tissue-level effect of triploidy on complement (blood), bactericidal (blood), and lyzozyme (blood and muscle) activities. However, a study with Atlantic salmon showed that complement activity took slightly longer to respond to, and recover from, a bacterial infection mimic (intraperitoneal injection with lipopolysaccharide) in triploids compared with diploids. Triploidy has been shown to have no effect on vaccine efficacy at the cellular and whole-animal level (**see also Hormonal Responses to Stress:** Impact of Stress in Health and Reproduction).

It is not clear whether triploidy affects disease resistance in fish under aquaculture conditions where it is impossible to control exposure levels and fish condition. However, under controlled experimental condition, triploids appear to have reduced disease resistance. For instance, although the effect of bacterial (*Vibrio anguillarum*) concentration delivered through intramuscular injection on mortality rates was found to be the same for unvaccinated triploid and diploid ayu (*Plecoglossus altivelis*), the average time to death was shorter in triploids. In unvaccinated coho salmon (*O. kisutch*) exposed to this same pathogen by immersion, the overall mortality was higher and average time to death shorter for triploids compared with diploids.

Nutrition and Growth

The earliest studies with triploid fish and amphibians assumed that they would grow larger than diploids as a result of their larger cells, as is often the case with gigantism in polyploid plants. This is clearly not the case for triploid vertebrates, including fish. A concomitant reduction in cell numbers balances any increase in cell size. Although it is unclear what the underlying homeostatic control mechanism is for balancing cell size and number, the end effect is that with the exception of the ovaries, organ size and body size are generally the same in juvenile diploids and triploids of the same age.

The physiology of nutrition and growth has received surprisingly little attention in triploids considering the focus of triploidy as a management tool in aquaculture. The limited data available are inconclusive as to whether triploidy affects food conversion efficiency, with some studies finding no effect and others finding both improved and reduced efficiency in triploids. At juvenile stages, there may be minor effects of triploidy on proximate composition and dietary digestibility coefficients, but again these are inconsistent among studies. The relationship between circulating IGF-I levels and growth rate is the same for triploids as for diploids. As juveniles, triploids generally grow no faster than diploids, with some studies finding equivalent growth rates and others finding triploid growth to be inferior. However, in species where diploids have low or no growth during the spawning period, triploid females tend to show continued growth. For this reason, long-term growth studies have often found triploid females to grow to be the largest fish (**see also Hormonal Responses to Stress:** Stress Effect on Growth and Metabolism and **Cellular, Molecular, Genomics, and Biomedical Approaches:** Growth Hormone Overexpression in Transgenic Fish).

Conclusions

The physiology of triploids has received far less research attention than that of diploids because triploidy is, for the most part, not a natural state in the life history of fishes. The fact that triploidy induction leads to sterility is of relevance to aquaculture, and much of the research on triploids has focused on economically important culture traits in a small number of commercially relevant species. However, the effects of triploidy on cell size and number make these fishes interesting models for basic research on how cell size and surface area to volume relationships affect physiological processes. Triploids tend to be similar to diploids in whole-animal tests of physiological performance; determining what sorts of compensatory mechanisms are involved in accommodating differences at the cell and tissue level should be a fruitful area of future research.

Glossary

Acromegaly Deformation of cranial structures typified by excess cartilage and bone growth.

Compensatory growth A period of accelerated growth following a period of stress such as food deprivation.

Gene construct A synthetic DNA molecule often containing regulatory and coding regions from different genes.

Orexigenic Stimulating appetite.

Pleiotropic Affecting multiple systems.

Promoter The upstream sequence of DNA which regulates the expression of the downstream coding sequence of the gene. The promoter may sometimes be as big or bigger than the gene itself. A so-called minimal promoter is the length of the promoter required to achieve expression of the gene, but without additional positive or negative elements.

Transgenic An organism possessing foreign DNA introduced by genetic engineering.

Brief History of Genetic Engineering in Fish

Genetic engineering, or transgenesis, involves the introduction of novel DNA into an organism by processes that do not normally occur in nature. Studies in the early 1980s showed that transgenic mice overexpressing growth hormone (GH) displayed a remarkable doubling of body size compared to nontransgenic littermates. These findings powerfully displayed the potential of genetic engineering to modify traits in vertebrates for use in basic science and for applied purposes.

Such growth enhancement was also recognized for its potential to enhance human food production in agriculture, and hence numerous reports soon appeared describing genetic engineering of commercially important livestock, including pigs, sheep, and cattle. Growth responses in these species were much more limited than those seen in mice, perhaps because these other species had long histories of genetic selection for enhanced growth under domestication (see below).

Genetic engineering of fish similarly began in the early 1980s (**see also Cellular, Molecular, Genomics, and Biomedical Approaches**: Transgenesis and Chromosome Manipulation in Fish). Currently, more than 35 species of fish have been genetically engineered with gene constructs designed to alter many traits, including growth, reproduction, disease resistance, and flesh quality. The first report of GH transgenesis in fish was from Dr. Zuoyan Zhu in Wuhan, China in 1986, working with the weather loach *Misgurnus anguillicaudatus*. In these studies, overexpression of GH genes increased growth in nontransgenic counterparts, and even beyond that seen in the transgenic mouse.

These early experiments kindled a large number of similar studies with fish, primarily using mammalian GH gene constructs, with the objective of generating strains with enhanced growth rate for potential use in aquaculture. Subsequently, the use of gene constructs comprised of fish sequences were developed, which in general functioned more effectively than nonpiscine gene constructs.

GH transgenesis remains a focus of activity for fish genetic engineering, generating strains for basic science investigations of growth physiology, behavior, ecology, and evolution. Some strains are also being actively pursued for application in aquaculture. However, globally, all transgenic fish are currently reared in specialized confinement facilities to prevent fish escape, and none are known to have entered natural environments.

Physiology of GH Is Well Known

Fish GHs, either purified from fish pituitaries or synthesized as a recombinant protein using bacterial expression systems, are active in stimulating growth in fish. Indeed, many fish possess a broad capacity to respond to GH family proteins (GH, prolactin (PRL), placental lactogen (PL), and somatolactin (SL)) from piscine and mammalian sources. Confirming an adequate response of a fish species or strain to GH is a critical research step that should be undertaken before embarking on a lengthy and expensive program to generate GH transgenic fish strains overexpressing this hormone.

Wild-type fish strains express normal GH genes at high levels in the pituitary gland and at very low levels in several other tissues. GH protein is stored in the pituitary. Its release is tightly regulated by neural controls and a suite of neuropeptides (growth hormone-releasing hormone (GHRH), somatostatin, gonadotropin-releasing hormone (GnRH), etc.) in response to internal metabolic (e.g., energy status and reproductive status) and external environmental (e.g., temperature, photoperiod, and food supply) cues that adjust growth rates to match seasonal and short-term conditions (**see also Hormonal Control of Reproduction and Growth**: Endocrinology of Fish Growth). GH is controlled through a negative feedback loop such that high circulating GH is capable of repressing its own synthesis in, and release from, the pituitary. This is an important feature of GH gene regulation, which becomes critical in the design of appropriate GH gene constructs for transgenesis (see below). GH functions by binding to the GH receptor which activates the janus kinases/signal transducers and activators of transcription (JAK/STAT) intracellular signaling systems to stimulate effector genes such as insulin-like growth factor-I (IGF-I). It is IGF-I that plays a primary role in stimulating growth, although some direct action of GH is also thought to occur.

How GH Transgenic Fish Are Made

To overexpress GH in transgenic fish, it is necessary to overcome the negative feedback controls that normally operate to limit GH production. In fact, simply adding additional copies of GH genes, with their native regulatory sequences, has not resulted in enhanced growth in transgenic fish. GH gene constructs therefore replace the normal regulatory sequences (promoters) of GH genes with those from other genes that are not sensitive to GH feedback regulation (see **Figure 1**). Promoters that have been used to drive GH sequences are often strong constitutive promoters – that is, those that are active at most times and in many cell types – and include those from the ocean pout antifreeze, metallothionein-B, β-actin, and cytomegalovirus-immediate early (CMV-IE) genes.

Figure 1 Example method of generating a gene construct for overexpression of GH. GH, growth hormone; Mt, metallothionein.

GH gene constructs are introduced into transgenic fish by mechanical (microinjection and particle bombardment), electrical (electroporation), or biological (pantropic viral) approaches. Microinjection has been primarily used, allowing introduction of small volumes (2–5 nl) of DNA through fine glass needles (tip sizes approximately 2–5 μm) into the cytoplasm of newly fertilized eggs where it later enters the nucleus and becomes integrated into host chromosomes. In most cases, transgenes appear to be very stable once integrated, and are faithfully transmitted to subsequent generations in a Mendelian fashion.

Growth Effects of GH Transgenes in Fish

The first laboratories to show strong growth acceleration in fish were those of Zuoyan Zhu with loach, and Garth Fletcher and Choy Hew with Atlantic salmon (*Salmo salar*). Growth effects of GH in transgenic fish actually can vary widely by strain and species, ranging from very little or no stimulation to as much as 34-fold (loach) or 37-fold (coho salmon, *Oncorhynchus kisutch*) increases in body weight (**Figure 2**). A general observation is that fish species that naturally grow fast (e.g., carps, catfish (*Ictalurus punctatus*), tilapia (*Oreochromis* sp.), and zebrafish (*Danio rerio*)) are more difficult to growth stimulate, probably because their metabolic machinery naturally operates at near full capacity. Cold-water species such as salmon and rainbow trout (*Oncorhynchus mykiss*) show very significant growth acceleration, primarily because control nontransgenic individuals are generally very slow growing.

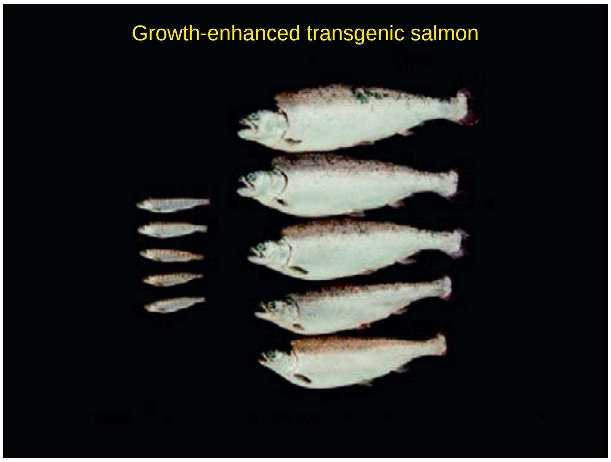

Figure 2 Normal (left) and GH transgenic (right) coho salmon at 1 year of age.

In coho salmon, GH transgenesis begins its action early, resulting in faster embryonic development and subsequent stimulation of growth through freshwater and marine growth phases. Thus, GH transgenesis can cause an overall compression of the life history and cause animals to undergo developmental stage changes at the wrong time of the year. Some GH transgenic fish (Pacific salmon) mature sexually at a younger age but with approximately normal body size, whereas others (rainbow trout) mature at a normal age, but with significantly larger bodies. What drives these differences is unknown at this time.

Expression of Transgenes and Endocrine Effects

GH transgenes drive the expression of GH mRNA in engineered fish, which in turn elevates production of GH protein. In many cases, the promoters that are used cause overexpression of GH mRNA in all tissues. However, this is not always the case as some (e.g., the ocean pout antifreeze and sockeye salmon (*Oncorhynchus nerka*) metallothionein-B promoters) express transgene mRNA at very different levels among tissues. Furthermore, species-specific differences in transgene function and effect exist. For example, an all-salmon DNA GH transgene driven by the metallothionein-B promoter stimulates growth strongly in salmon and charr (*Salvelinus alpinus*), but has no effect in tilapia. The reason for this variability is being actively investigated.

In part due to the difficulty in developing assays for GH hormone for various fish species, few have attempted to examine for elevated production of GH protein in the large number of GH transgenic fish species. Where examined, circulating GH is indeed elevated, but the increase relative to wild type can be slight (e.g., ~1.5-fold) or as much as 40-fold (with certain constructs in coho salmon). The large variance in apparent induction level of GH, particularly in salmonids, arises in part from the strong natural fluctuations in levels of this hormone seasonally. GH is found at very low levels in winter in nontransgenic fish, but remains constitutively expressed in GH transgenic fish. Expression of GH in the pituitary of salmon is strongly repressed in older GH transgenic fish (due to negative feedback regulation – see above), resulting in diminished pituitary size and dampening of brain/pituitary regulation of growth.

IGF-I levels can also change in GH transgenic fish. In salmon with GH expression driven by the metallothionein-B promoter, IGF-I mRNA is elevated in liver and other tissues, and circulating levels of hormone are increased. By contrast, IGF-I levels may be higher or lower than wild type in salmon when GH expression is driven by the ocean pout promoter. In GH transgenic tilapia, IGF-I mRNA and protein increase in several tissues, but circulating serum IGF-I levels are lower, perhaps because higher IGF-I-binding protein levels are also found. Tissues removed for culture (**see also Cellular, Molecular, Genomics, and Biomedical Approaches**: Culture of Fish Cell Lines) from GH transgenic salmon can continue to show enhanced growth (in the form of synthesis of cartilage) *in vitro*, revealing that local (paracrine) effects are functioning. GH receptor gene expression is also induced in GH transgenic salmon, which may facilitate signal transduction and stimulation of IGF-I gene expression. Nutritional modulation of IGF-I expression also occurs such that GH transgenic fish fed a wild-type ration level show normal levels of this hormone. Thus, the available data indicate that there are construct and species-specific effects, but in general, elevated GH arising from extrapituitary expression of the transgene stimulates IGF-I gene expression and protein production in liver and other tissues, which in turn act in paracrine and/or endocrine fashions to stimulate growth, provided sufficient intake of energy occurs.

Other critical hormones are involved as well. For example, triiodothyronine (T3), a thyroid hormone that has strong positive effects on growth, is elevated in GH transgenic salmon due to an inhibition of T3 degradation rates. T3 levels in GH transgenic fish are unaffected by ration level suggesting a more direct action of elevated GH, as opposed to being mediated by secondary signals such as IGF-I.

In addition to effects on specific genes in the GH/IGF-I axis, microarray analysis (a technique that allows examination of the mRNA levels of thousands of genes simultaneously) has shown that GH transgenesis in fish affects the expression of many other genes (**Figure 3**), including those for lipid metabolism, iron homeostasis,

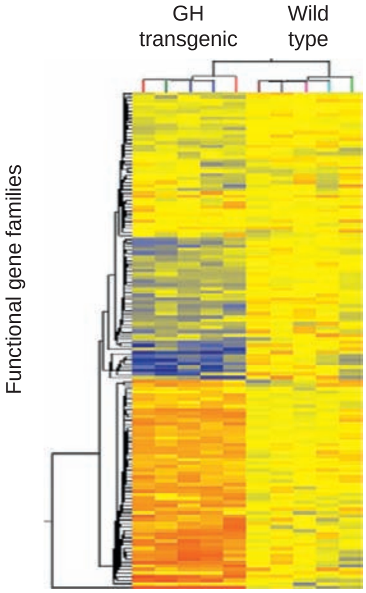

Figure 3 Heat map and hierarchical clustering of liver gene expression differences between wild-type (left five lanes) and GH transgenic salmon (right five lanes). Red bars indicate increased, and blue decreased, gene expression relative to wild type.

mitochondrial function, carbohydrate metabolism, cellular proliferation, and innate immunity. By comparing gene expression patterns among wild-type, fully fed GH transgenic (fast growing), and ration-restricted GH transgenic (growing at wild-type rates) salmon, it is apparent that some genes are directly affected by GH overexpression and some are indirectly influenced by growth rate. Thus, at the cellular level, GH expression has very broad pleiotropic effects on many pathways that are expected to influence physiological, morphological, and behavioral phenotypes of the organism, as discussed below.

Phenotypic Effects – Morphology

In addition to changes in body size with age, GH transgenesis can cause disproportionate development of organs and tissues in fish. In many vertebrates, overproduction of GH leads to an acromegaly syndrome. A striking example of this occurs in some GH transgenic salmon strains that show excessive overgrowth of cartilage in the cranium and operculum (**Figure 4**). Some deformation of head shape exists in GH transgenic tilapia and catfish. Many strains do not show these phenotypes, or are only mildly affected, suggesting that an appropriate level of GH expression is necessary in GH transgenic fish to maximize growth without inducing abnormalities (**Figure 5**).

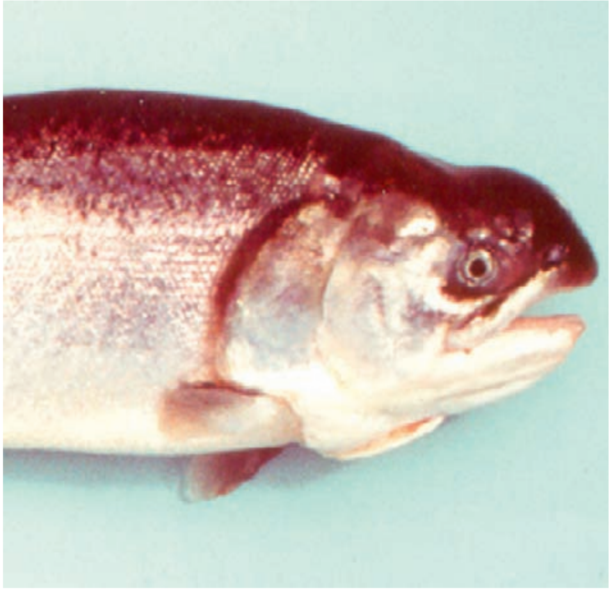

Figure 4 Phenotype of a severely acromegalic GH transgenic coho salmon. Reproduced from Devlin RH, Yesaki TY, Donaldson EM, and Hew CL (1995) Transmission and phenotypic effects of an antifreeze/GH gene construct in coho salmon (*Oncorhynchus Kisutch*). *Aquaculture* 137: 161–169, with permission from Elsevier.

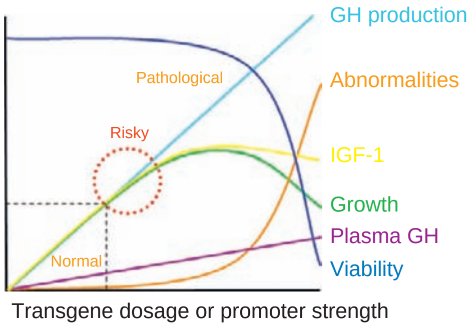

Figure 5 Relationship between GH expression, growth, viability, and abnormalities. Boxed area indicates zone where stimulation can occur without inducing pathologies.

In salmon, treatments of wild-type fish with T3 can lead to a similar acromegaly phenotype. In GH transgenic fish, the severity of such deformations can be reduced through treatment with anti-thyroid compounds (e.g., 6-n-propyl-2-thiouracil), suggesting that the acromegaly is mediated at least in part by T3.

Changes in the morphologies of specific organs or tissues have also been noted in GH transgenic fish. Smaller average cell size has been observed in GH transgenic salmon muscle, indicating that growth is occurring primarily by hyperplasia, rather than by hypertrophy, as it occurs in mammals. In GH transgenic Atlantic but not coho salmon gill surface area is reduced relative to wild fish, whereas gut surface area is increased in both species. The enhancement of gut functional size in GH transgenic coho salmon arises from a direct effect of the GH transgene, but also is affected indirectly by their enhanced food intake (food intake is known to influence gut development in many other vertebrates). Enlarged hearts have also been noted in GH transgenic Atlantic salmon resulting in enhanced cardiac output, and reduced eye and brain size occurs in GH transgenic Pacific salmon. Thus, it is clear that some allometric development of organ systems arises from GH transgenesis in fish, presumably due to differential responsiveness to, or nonuniform expression and paracrine effect of, GH among tissues.

General Viability and Immunology

The general viability (under culture conditions) of GH strains can vary widely, and depends on the level of expression from the transgene (**Figure 5**). Strong promoter constructs and certain strains with weak promoters can produce fish that are grossly deformed (see above) and have poor viability. The viability of strains with a more normal morphologically can approach or equal that of wild-type fish. Viabilities of GH transgenic fish are influenced by environmental conditions, for example, seminatural conditions with predators or low food supplies can reduce survival of these animals (see below).

GH overexpression can also affect disease processes in GH transgenic fish. Treatments of nontransgenic fish and fish cells with GH protein have been reported to enhance disease resistance and/or immune function. In GH transgenic carp, lysozyme and serum bactericidal activity are elevated, suggesting that disease resistance may be enhanced. By contrast, GH coho salmon do not show elevated lysozyme and other immune parameters. When challenged with the bacterial pathogen *Vibrio anguillarum*, survival is reduced, indicating a reduced innate disease resistance. However, GH transgenic fish surviving an initial bacterial infection show high resistance to the same pathogen, indicating that their acquired immune response still functions effectively. It is apparent that different species and strains respond distinctly to GH with respect to disease resistance.

Nutritional Requirements and Energy Use

Enhanced growth rate of GH transgenic fish is fueled by elevated energy intake and utilization. In GH transgenic salmon, feed intake (adjusted for body size) is as much as threefold greater per day than that of nontransgenic fish, depending on development stage and strain. Feed utilization (conversion efficiency) is enhanced by between 10% and 20%. Other species (such as tilapia, carp, and loach) also increase feed intake. GH transgenic rohu and one strain of GH transgenic tilapia, however, reduce feed intake. Instead, in both of these cases, feed conversion in GH transgenic fish was strongly enhanced (as much as fourfold for the tilapia), a physiological transformation that supported their enhanced growth with reduced feed intake.

In GH transgenic carp and salmon, feed intake and effects on conversion efficiency are strongly dependent on the composition of the feed. When protein levels in the feed are low, GH transgenic carp primarily enhance growth through higher food intake, whereas feed conversion efficiency is enhanced when protein levels are high. GH transgenic salmon appear to possess a new set point for energy intake, and grow at similar rates by increasing feed intake to meet energy demands when provided with low-energy feeds. However, eventually a threshold is reached where intake of very low-energy feeds is physically constrained by gut capacity, and maximal growth cannot be sustained. By contrast, feed conversion efficiency is enhanced with provision of high-energy feeds. In both GH transgenic and control carp, temporary feed restriction can lead to a compensatory growth response. By contrast, growth compensation is not observed in a very fast growing strain of GH transgenic coho salmon. Such differences between carp and salmon may depend on the levels of growth stimulation between the species and strains.

Starvation trials, and feeding trials using diets containing different levels of lipid, protein, and carbohydrate, have shown that GH transgenic salmonids, tilapia, and carp preferentially utilize lipid as an energy source, sparing protein for growth. When available energy intake is restricted, GH transgenic salmon reduce levels of body lipid stores, consistent with the lipolytic action of GH, whereas when feed availability is not limited, body lipids are much higher than in wild-type salmon. Excess deposition of fat arises from the behavioural stimulation of appetite by GH (see below), which results in greater feed intake than is required to support somatic growth.

Oxygen Uptake, Exercise, and Energy Use

A basic question surrounding GH transgenic fish energetics is whether their growth rate is driven by an obligate enhancement of metabolic processes, or do they possess increased scope that enables opportunistic use of increased energy when available? GH transgenic coho salmon show elevated oxygen uptake during exercise and during food absorption, but not during routine activity, suggesting they are not forced into a high metabolism at all times. By contrast, GH transgenic Atlantic salmon show elevated oxygen uptake during routine culture, during exercise, or following 24 h of starvation, indicating that they maintain high metabolic rates for more extended periods. GH transgenic tilapia also show elevated oxygen uptake during routine activity or during exercise.

The interaction between growth, feed intake, and energy stores can complicate investigation of metabolic rates. For example, GH transgenic fish consume more food and deposit more body fat prior to experiments, and thus remain in a positive energy balance for an extended period compared to control animals. Following prolonged starvation of GH Atlantic salmon, oxygen uptake eventually drops to normal levels, similar to the response seen in coho salmon. In GH Atlantic salmon, no difference in tolerance to low oxygen has been detected despite having a higher critical oxygen uptake level. The situation is more complex in GH transgenic carp, where family differences in tolerance to low oxygen exist, suggesting only a modest effect of the transgene relative to normal variation associated with this trait. During embryonic development (where available energy is fixed), GH transgenic coho salmon eggs are less able to survive periods of hypoxia, suggesting their demand or transport ability for oxygen differs from wild type.

Exercise capabilities of GH transgenic fish have been measured for tilapia, salmonids, and carp. In general, GH transgenic fish reduce maximum prolonged swimming speed (U_{crit}) and increase oxygen requirement during exercise. However, rearing conditions and age of fish can strongly influence these effects (e.g., U_{crit} has been found to be unaffected or reduced for the same strain of GH Atlantic salmon in different studies). Structural (e.g., muscle fiber size and body morphology) and metabolic changes in muscle discussed above are likely responsible in part for reduced swimming capacity.

The significant changes in growth and energy use in GH transgenic fish are supported by changes in levels of metabolic enzymes. While some inconsistencies in the available data are apparent (perhaps arising from differences in species, strain, ration level, fish age), in general changes reflect an enhanced ability to utilize available energy. For example, in juvenile GH transgenic tilapia and salmon, enzymes involved in amino acid catabolism (for energy production) increase both in liver and muscle, and in salmon, enzymes involved in carbohydrate use increase. Equally, however, many enzymes are unaffected by GH transgenesis, indicating that their normal levels allow sufficient flux through metabolic pathways to support the enhanced growth rates seen in these animals.

GH strongly influences osmoregulatory ability in fish, particularly in species such as salmon, which undergo a parr-to-smolt transformation (a physiological adaptation to allow ion regulation in marine conditions) (**see also Osmotic, Ionic and Nitrogenous-Waste Balance**: Mechanisms of Gill Salt Secretion in Marine Teleosts). Smolt development is influenced by body size and hence growth, and thus GH transgenic salmon can achieve smolt status much sooner than wild-type strains. Wild-type coho and Atlantic salmon normally smolt in their second spring at approximately 18 months postfertilization, whereas GH transgenic strains can smolt when 6 months old during their first summer. This precocious transformation is accompanied by typical body silvering (**Figure 2**), and enhanced osmoregulatory ability (as determined by plasma sodium levels and gill Na^+-K^+-ATPase activity levels) that facilitate survival following transfer to seawater. Detailed studies in GH transgenic Atlantic salmon show that smolt development occurs under a wide range of environmental conditions, in contrast to wild-type salmon which require relatively specific temperatures and photoperiods to initiate this change in physiology. In a euryhaline tilapia species, GH transgenesis also facilitates osmoregulatory tolerance to seawater conditions.

Behavior

Strong enhancement of feeding motivation and appetite (see **Video Clip 1**) support the metabolic and growth effects of GH overexpression. Many GH transgenic fish strains consume more food than nontransgenic fish of the same size (see above for exceptions), and for salmon and carp, this translates into higher feeding motivation such that GH transgenic fish can effectively outcompete wild-type fish for food in their environment. GH transgenic fish can eventually become satiated, but they return to active feeding more rapidly than nontransgenic fish, and do so even when their guts are filled, suggesting dominance of brain-driven regulation of short-term feeding activity (as opposed to peripheral controls such as stomach stretch receptor or anorexigenic peptide signals). A striking feature of GH transgenic coho salmon is they continue to feed at very high levels throughout all seasons, whereas nontransgenic salmon strongly reduce appetite and feeding motivation during the fall and winter in response to environmental conditions, indicating that GH transgenesis strongly alters central regulation of feeding.

The regulation of feeding behavior involves many orexigenic and anorexigenic neuropeptides and neurotransmitters. In nontransgenic fish, neuropeptide Y (NPY) and cholecystokinin (CCK) positively and negatively influence appetite, respectively, and NPY mRNA levels increase in the preoptic areas of the brain in starved salmon. However, the expression of genes for these two neuropeptides is unaffected in GH transgenic salmon brain subregions, suggesting more complex control (e.g., perhaps at the level of specific brain nuclei). Gut CCK mRNA levels differ between winter and summer more strongly in nontransgenic than GH transgenic fish, and suppression of appetite with the CCK inhibitor devazepide is less effective in GH transgenic fish, suggesting that seasonal regulation of feed intake is dampened (see discussion above regarding alteration of brain/pituitary-level control of growth).

GH mRNA expression is enhanced in multiple brain regions in GH transgenic Pacific salmon. However in

Atlantic salmon, intracerebroventricular (ICV) injection of GH protein does not stimulate feeding behavior, suggesting a more indirect mode of action for GH-mediated appetite stimulation. As indicated above, IGF-I levels (both circulating hormone and tissue mRNA) are elevated in fully fed GH transgenic fish but only when they are fed satiating rations. GH transgenic salmon fed wild-type ration levels have normal levels of IGF-I, but still retain the strongly enhanced feeding behavior, indicating that circulating IGF-I is not directly regulating feeding behavior. ICV injection of GH however does influence swimming behavior (by modulating dopaminergic stimulation in the brain), a response similar to that seen in GH transgenic fish, which show more rapid movement in response to feeding, and greater tendency to disperse in naturalized environments.

In nature, foraging activity increases contact with predators, and consequently, in order to maximize fitness, many organisms balance the need to acquire food resources (to allow growth and reproduction) with the risk of dying from predation. A consequence of enhanced feeding motivation in GH transgenic fish is that they spend more time foraging than do wild-type fish, and are more willing to expose themselves to predation risk (**Figure 6**).

In naturalized conditions, GH transgenic fish suffer greater mortality in the presence of predators, indicating a shift away from the evolved foraging/predation risk balance found in wild-type fish. This effect is exacerbated by low food supplies (which requires increased foraging), or by early emergence from the safety of natal redds (which exposes GH transgenic fish to predators first). Under highly competitive conditions with low food supplies, GH transgenic fish engage in cannibalism, causing crashes of small experimental populations.

Reproduction can also be influenced by GH transgenesis, both with respect to spawning ability and gamete characteristics. In medaka (*Oryzias latipes*), GH transgenic males grow larger and have a breeding advantage over wild type, whereas in salmon, GH males and females have impaired spawning ability. Sperm quality and quantity is reduced in GH transgenic males, while in GH transgenic females egg size is reduced and fecundity increased. Rearing conditions can strongly affect the development of reproductive capabilities, and thus knowing the effect of GH transgenesis alone is difficult, particularly for larger species kept in captivity.

Application in Aquaculture, and Environmental Risk Assessments

GH transgenic fish have considerable potential to enhance production efficiency in aquaculture by shortening production times and enhancing feed conversion efficiency. For many species of fish, genetic engineering can generate strong improvements in strain performance much faster (two to three generations) than can selective breeding or domestication. However, for some species (e.g. rainbow trout) that have been long domesticated and are already growing very rapidly, adding GH transgenes has a much reduced effect compared to the response seen in slow-growing wild-type strains (**Figure 7**). Analyses of gene

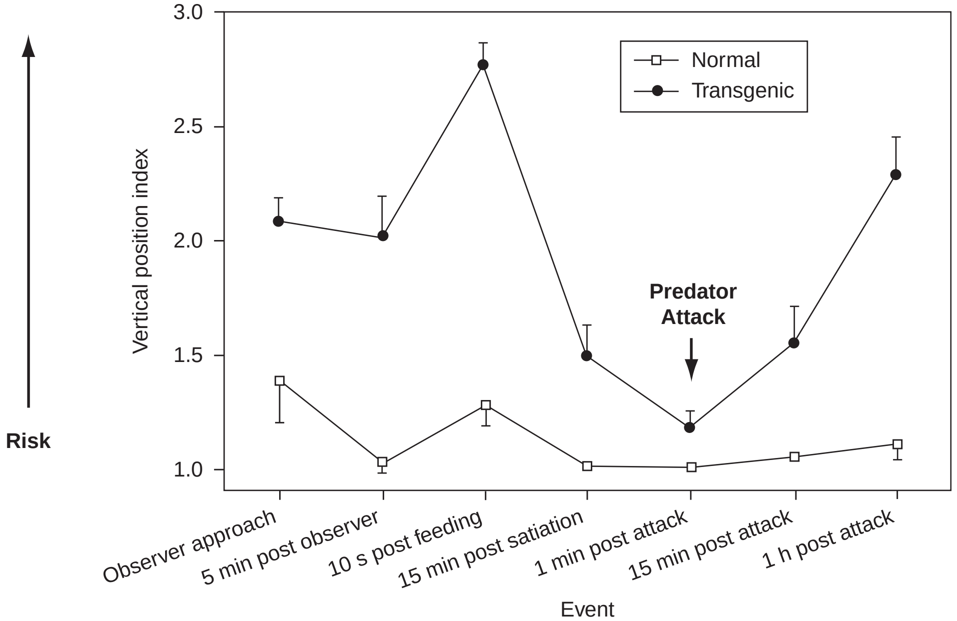

Figure 6 Risk-taking behavior of GH transgenic and wild-type salmon. Redrawn from Sundström LF, Devlin RH, Johnsson JI, and Biagi CA (2003) Vertical position reflects increased feeding motivation in growth-transgenic coho salmon (*Oncorhynchus Kisutch*). *Ethology* 109: 701–712.

expression (using microarrays; **see also Cellular, Molecular, Genomics, and Biomedical Approaches**: Global Gene Expression Profiling in Fish) and growth-modulating hormones (GH, IGF-I, T3) show that domestication and GH transgenesis actually modify physiological pathways in similar ways; thus, growth stimulation of domesticated strains by additional overexpression of GH from a transgene may be anticipated to be dampened.

A major issue associated with GH transgenic fish for use in aquaculture is the potential environmental risks they may pose should they inadvertently escape from research or production facilities and enter nature. Concern has centered mainly on the potential ability for GH transgenic fish with novel phenotypes (such as heightened feeding motivation) to outcompete other organisms in ecosystems and alter community structure and/or biodiversity. Under some conditions, GH transgenic fish have been hypothesized to be able to cause extinctions of populations (known as a Trojan Gene effect) through the interaction of pleiotropic phenotypes (e.g., high mating success driving the transgene into populations

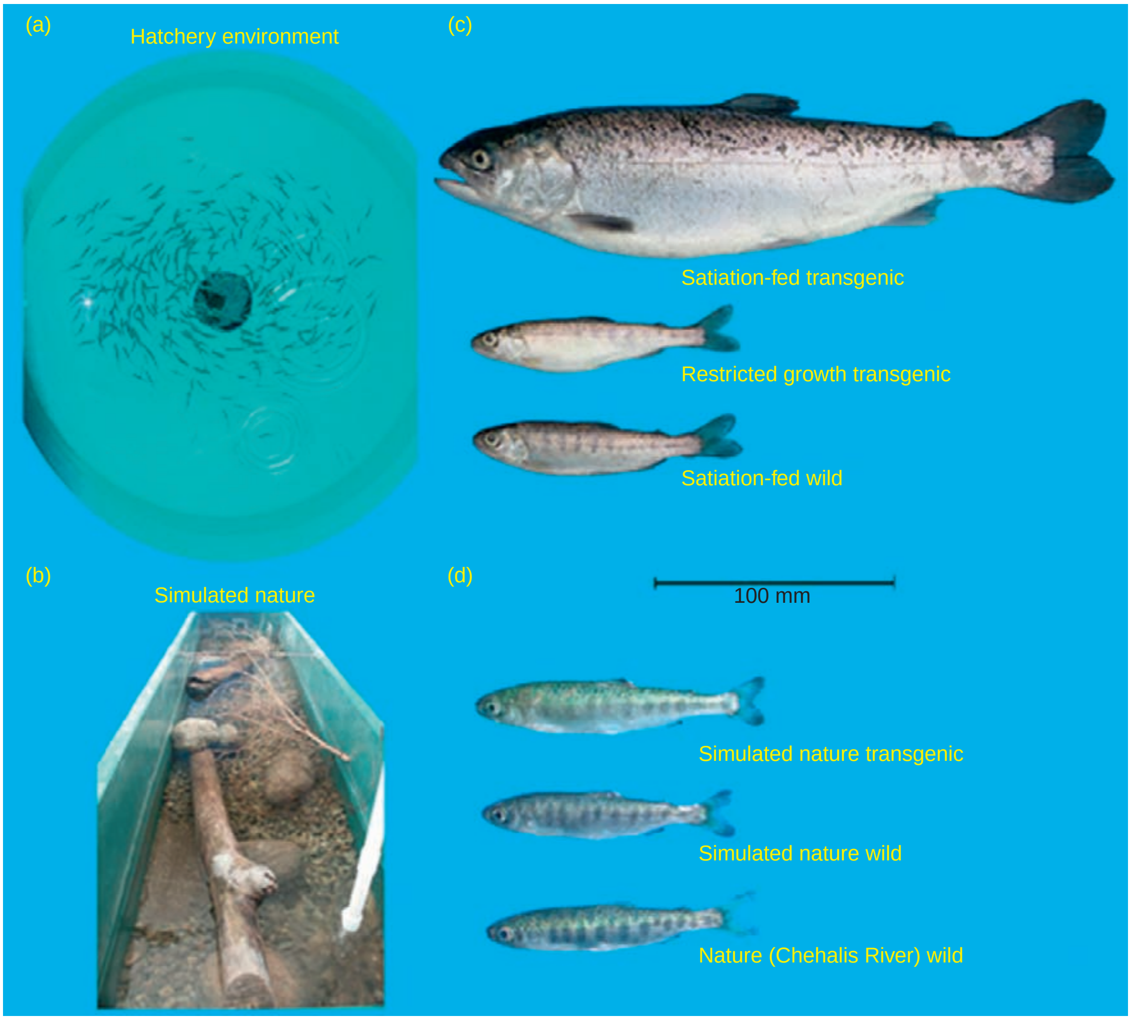

Figure 8 Influence of rearing environment on growth in GH transgenic coho salmon. Note GH transgenic fish show reduced growth under naturalized conditions. Reproduced From Sundström LF, Lohmus M, Tymchuk WE, and Devlin RH (2007) Gene–environment interactions influence ecological consequences of transgenic animals. *Proceedings of the National Academy of Sciences of the United States of America* 104: 3889–3894.

combined with poor viability which simultaneously reduces survival).

The effects of GH transgenic fish are expected to be highly dependent on their fitness in nature (i.e., ability to survive and reproduce) as well as their interaction with various ecosystem components (e.g., prey, predators, and pathogens). At this time, predicting the effects of GH transgenic fish in nature based on data generated in laboratories is difficult, since many of the traits affecting fitness and consequences are also affected by rearing and experimental environmental conditions (**Figure 8**). Due to such uncertainties, containment methods using physical approaches (e.g., land-based culture systems) or biological methods (e.g., sterilization by triploidy or transgenic methods) are being explored to minimize exposure of GH transgenic fish to an ecosystem, and potentially allow safe application of this technology outside of laboratory facilities.

Glossary

Androgenesis Formation of offspring possessing only paternal genetic information.

Gynogenesis Formation of offspring possessing only maternal genetic information; a type of parthenogenesis where embryogenesis is triggered by the presence of sperm, although the sperm does not contribute any genetic material.

Heteromorphic chromosomes A chromosome pair with visible size differences.

Homomorphic chromosomes A chromosome pair with no visible size differences.

Sex chromosome A chromosome whose presence or absence correlates with the sexual identity of the organism.

Sex determination Genetic or environmental process whereby the gender (male or female) is established in an individual. In most species, sex determination depends on the genotype (genotypic sex determination, GSD), but in some it depends on the value of some environmental variables during a specific developmental stage (environmental sex determination, ESD), with temperature being the most common one (temperature-dependent sex determination, TSD). Even in species with ESD, there is always a genetic component controlling sex determination.

Sex differentiation Process whereby a sexually undifferentiated gonad transforms into a testis or an ovary, according to genetic information, the influence of the environment or both. Sex differentiation results in the gonadal or phenotypic sex.

Introduction

The study of sex chromosomes and sex-linked traits in the fruit fly *Drosophila melanogaster* by Calvin Bridges around 100 years ago provided the ultimate proof that genes were associated with chromosomes. In the following years, the genes that determine sex in *D. melanogaster*, the nematode *Caenorhabditis elegans*, and mammals were elucidated. Despite the conservation in many developmental mechanisms observed in these animals, the genes controlling sex determination surprisingly were not well conserved in evolution. As an example, the mammalian sex determination gene *SRY* (sex-determining region on the Y chromosome*),* which acts as a dominant male-determining gene on the Y chromosome, is present only within therian mammals (all mammals except monotremes). Thus, all other animals determine sex through different means. Some animals harbor a different sex determination gene, while the others use environmental stimuli to determine sex, to name two examples.

The primary sex determination signal sets up a cascade of events triggering sex differentiation, that is, the development of sexually dimorphic structures or morphologies (**see also Hormonal Control of Reproduction and Growth**: Endocrine Regulation of Fish Reproduction; **Reproduction**: The Diversity of Fish Reproduction: An Introduction; **The Reproductive Organs and Processes**: Anatomy and Histology of Fish Testis; Regulation of Spermatogenesis). The initiation of development of the testis or ovary from an undetermined gonadal primordium is typically the first hallmark of sex differentiation. Comparative analysis of gene expression in many vertebrate species has led to the discovery that many genes functioning in sex differentiation are expressed in the developing gonads, oftentimes exhibiting sexually dimorphic expression. Therefore, it is likely that the genes regulating sex differentiation of the vertebrate gonad have conserved roles in this process despite the differences in the primary sex determination cue.

In fish, the methods by which sex is determined vary widely across species. Sex can be determined by genomic inputs, environmental inputs (such as temperature or social cues), or by a combination of these. Certainly, the endocrine system plays a major role in sex determination (**see also Hormonal Control of Reproduction and Growth**: Endocrine Control of Sex Differentiation in Fish). However, how the endocrine system and genetic or environmental signals (**see also Social and**

Reproductive Behaviors: Socially Controlled Sex Change in Fishes) integrate to give the final outcome of male or female sexual fate is not well understood. This article discusses the genetic control of sex determination and gonadal sex differentiation.

Genetic Sex Determination

The genome oftentimes provides a significant contribution to the determination of sexual fate in fish. Chromosomal sex determination, where one gene commonly acts as the primary sex determination cue, is prevalent. Another mechanism through which sex can be genetically determined is polygenic sex determination, where the combination of multiple genes tips the fate choice toward either male or female. The genetic control of sex determination can be elucidated by karyotype analysis, identification of sex-linked traits, or through genetic experiments.

Chromosomal Sex Determination

Many fish species utilize chromosome-based sex determination mechanisms. In chromosomal sex determination, a single gene commonly regulates sex determination. The chromosome harboring this gene is dubbed the 'sex chromosome' as its inheritance correlates with sex due to coinheritance with the sex determination gene. Chromosomal sex determination generally comes in two varieties: XX/XY and ZZ/ZW. In the former case, males are heterogametic (XY) and females are homogametic (XX). In the latter, females are heterogametic (ZW) and males are homogametic (ZZ). It is also possible for one sex to be lacking a chromosome altogether, for example, some animals have XX/X0 or ZZ/Z0 sex determination. Many examples of chromosomal sex determination exist in fish; some are given in **Table 1**.

Chromosomal sex determination may be identified by cytogenetic techniques if one sex chromosome appears visibly different from the other. When the sex chromosomes are heteromorphic, large size differences are apparent through staining of chromosomes. When the differences are very small between the sex chromosomes, synaptonemal complex analysis can identify unpaired regions that could indicate unique sequences on the chromosome in only one sex. Fluorescent *in situ* hybridization (FISH) can also be used to visualize sequences that are sex specific. Using this method, sex-specific loci or repetitive elements mark the sex chromosomes. In addition to cytogenetic techniques, or in cases where no visible differences can be detected by the above techniques, analysis of sex-linked traits or genetic experiments has revealed the sex determination mechanisms of many fish (see below).

An indication of chromosomal sex determination is the coinheritance of a trait or character with sex, a phenomenon dubbed 'sex linkage'. When a trait or character is coinherited with the Y chromosome, it segregates from fathers to sons. Conversely, when the trait or character is linked to a W chromosome, it segregates from mothers to daughters. Thus, sex linkage can reveal the chromosomal nature of sex determination. These traits or characters can be visible traits (e.g., pigmentation or ornamentations), protein signatures, or DNA sequences. One must take care when using visible traits or protein signatures to assess sex linkage as these can also be influenced by sex-specific hormonal regulation. Therefore, it is essential to experimentally determine if the trait is sex specific as a result of coinheritance with the sex determination locus or due to the sex-specific hormone regulation.

Genetic experiments have been successfully used to discover sex determination mechanisms. Fish that consistently yield 1:1 sex ratios are likely to have chromosomal sex determination; those that deviate from 1:1 sex ratios probably have polygenic or environmental sex determination. Alternatively, they may have chromosomal sex determination, but have additional genetic or

Table 1 Examples of genetic sex determination systems

environmental factors that can override the predominant sex determination gene. For those animals with suspected chromosomal sex determination, whether an XY or ZW system is functioning can be elucidated by performing experiments using hormone-induced sex-reversed fish or by inducing gynogenesis or androgenesis. In the former experiment, matings of sex-reversed fish with normal fish give predictable sex ratios that reveal the chromosomal mechanism (see **Figure 1** for detailed description). In the latter experiments, gynogenetic or androgenetic fish are produced resulting in fish with all genetic material derived from a female or male fish, respectively. Again, predictable sex ratios arise depending on the chromosomal mechanism of sex determination (**Figure 2**).

Multifactoral Sex Determination

Polygenic sex determination

Oftentimes sex ratios are not 1:1 or the experiments outlined in **Figures 1** and **2** yield unpredicted outcomes. This may indicate a polygenic sex determination system where the combined effect of multiple genes determines sex. The presence of polygenic sex determination is difficult to prove as unpredictable sex ratios might also arise due to environmental influences. A good indication of polygenic sex determination is through pair-wise matings or through analyses of androgenic or gynogenic fish. Successive matings of individual pairs of fish can reveal whether or not sex is genetically determined. Whenever possible, the progeny should be reared under constant conditions to eliminate the possibility of environmental influences. If successive matings between individual pairs generally give rise to clutches with consistent sex ratios, then there are probably genetic factors determining sex. To confirm this result, two experiments can be significant. First, fish resulting form gynogenesis or androgenesis will give unpredictable sex ratios. For example, in zebrafish (*Danio rerio*), androgenesis has been reported to give rise to nearly all male populations, nearly all female populations, or mixed-sex populations. This discrepancy might be due to the genetic makeup of the parent fish being used. A key experiment for proving that there is a genetic contribution to sex is by conducting selection experiments. One selects for populations with higher male-to-female sex ratios, for example, over successive generations. If the high male-to-female sex ratio increases

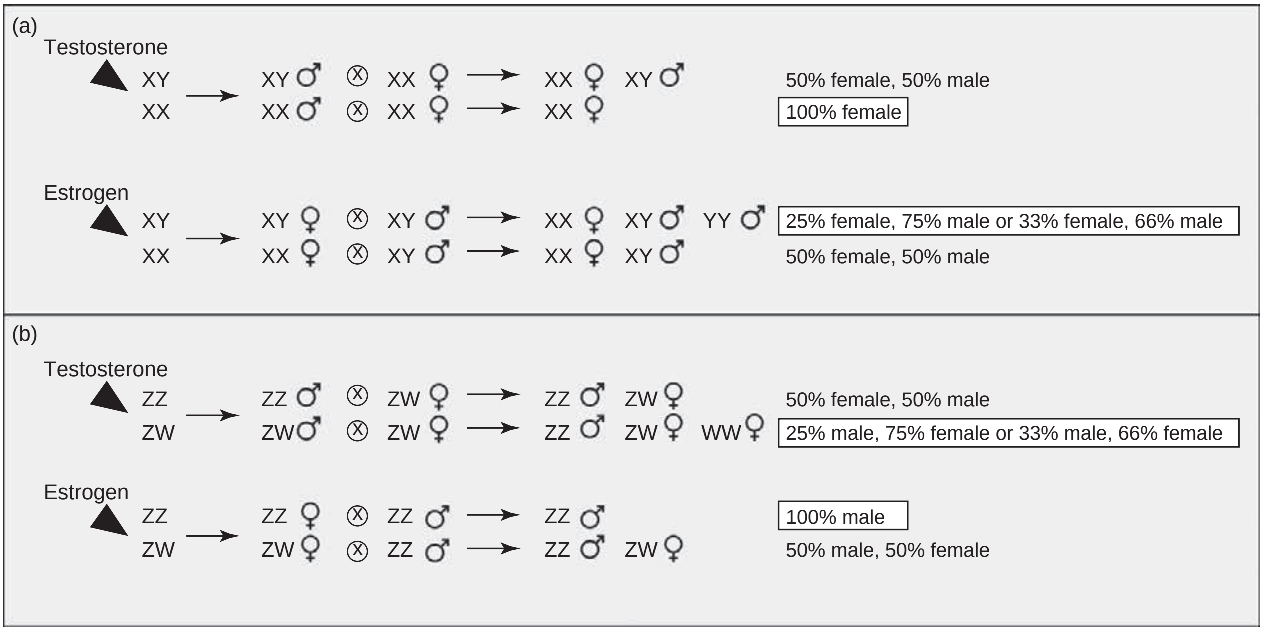

Figure 1 Hormone treatment and crossing scheme to decipher the mechanism of sex chromosome determination. Fish are treated with hormones prior to sex differentiation. At the time of treatment, the sex of the fish is not discernable; thus, the population is mixed XX and XY or ZZ and ZW. The fish treated with testosterone all develop into males, whereas those treated with estrogens all develop as females regardless of the sex chromosome content. Hormone-treated fish are individually crossed to normal males or females. In all experiments, half of the resulting clutches will give rise to 50/50 sex ratios. These are derived from the non-sex-reversed individuals in the treatment (e.g., XY males in the testosterone-treated group) and are not informative. However, those clutches giving rise to sex ratios deviating from 50/50 can reveal whether the sex chromosome system is XY or ZW. These informative clutches are highlighted. (a) In organisms with an XY sex determination system, sex reversal with testosterone treatment followed by crossing to natural females gives rise to some clutches that are 100% female. Treatment with estrogen followed by crossing to natural males leads to clutches with sex ratios of either 25/75% female to male when YY individuals are viable or 33/66% female to male when the YY chromosomal content is lethal. (b) In organisms with a ZW sex determination system, the resulting sex ratios from hormone-treated sex-reversed fish followed by crossing to natural males and females is counter to those observed from organisms with XY sex determination.

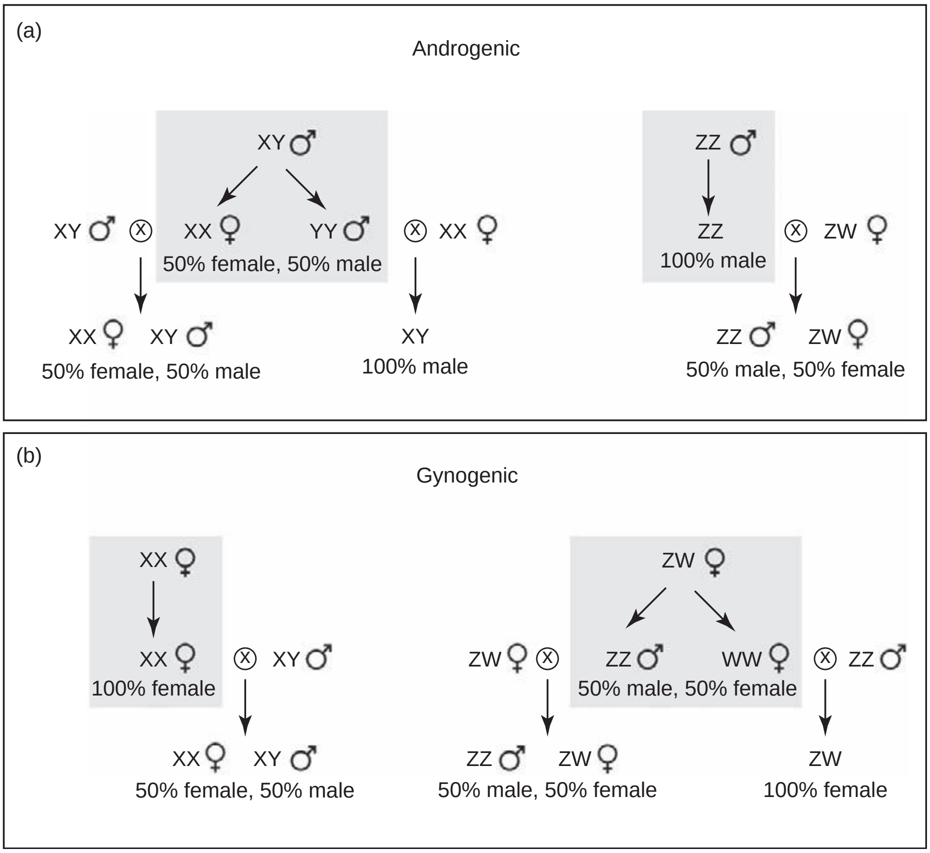

Figure 2 Use of androgenesis and gynogenesis to determine the sex chromosome system. Production of fish from diploid gametes derived from male or female individuals' results in predictable sex ratios depending on the sex chromosome mechanism (shown in the shaded boxes). Crossing of the resulting fish to natural males or females can confirm the sex chromosome contents through production of predictable sex ratios, shown outside of the shaded boxes. (a) Diploid gametes from XY male fish give rise to populations with 50/50 sex ratios of XX females to YY males offspring, assuming viability of YY individuals. By contrast, those resulting from ZZ males give 100% ZZ males. (b) Gynogenesis results in 100% females when the parent females have XX sex chromosomes or 50/50 sex ratios when parent females have ZW sex chromosomes, assuming viability of WW females.

over each generation, then it is likely that the researcher has enriched for male-determining loci or alleles. This is a clear indication that multiple genetic factors determine sex.

Modifiers

It is not uncommon to find exceptions to the above sex determination mechanisms. For example, in fish with chromosomal sex determination, a small percentage of XX males may be present in the population. When different strains are available, the percentage of these exceptional males is often strain dependent, indicating genetic modifiers. For example, in medaka (*Oryzias latipes*), some strains produce more than 10% XX males, whereas others exhibit no XX males. This strain dependency indicates an autosomal gene or genes that can control sexual fate in the absence of the predominant sex determination gene. As yet, the genes that act as modifiers to sex determination have not been identified. In addition to genetic modifiers, environmental stimuli can also override the genetic sex determination signal, leading to exceptional males or females.

Sex Determination in Medaka

The medaka fish have been studied for decades with respect to various aspects of fish biology including sex determination. Medaka have an XY sex determination system with a dominant male-determining gene on the Y chromosome determining male sexual fate. The Y chromosome is homomorphic, but can be visualized by FISH using Y-specific probes. Currently, it is the only fish for which the sex determination gene has been identified.

The medaka sex determination gene is called *DMY* (also known as *dmrt1bY*). *DMY* is a homolog of the doublesex and mab-3 related transcription factor 1 (*DMRT1*) gene. *DMY* and *DMRT1* encode transcription factors containing a conserved zinc finger DNA-binding domain, dubbed the 'DM domain'. The vertebrate *DMRT1* gene name is derived from its relation to the doublesex gene in the fruitfly *D. melanogaster*, which is essential for both male and female sex determination, and the male abnormal-3 (*mab-3*) gene in the nematode *C. elegans*, which is important for specification of male-specific cell fates. In vertebrates, *DMRT1* is known to function as, or to be associated with, sex-specific development of many animals including chicken, alligator, mouse, and humans. Medaka possess two *DMRT1* paralogs, *DMRT1* and *DMY* (also known as *DMRT1a* and *DMRT1bY*, respectively). *DMY* is expressed in the male gonad during the time window of sex determination and through adulthood. The autosomal *DMRT1* gene is expressed in the same gonadal cell types as *DMY* but at a later time point, after sex is determined.

The medaka Y chromosome arose between 10 and 18 million years ago through duplication of the *DMRT1*-containing region and insertion onto another chromosome. The duplicated *DMRT1* gene subsequently evolved to become the *DMY* sex-determining gene, resulting in a Y chromosome with a small Y-specific region. This region contains 258 kb of sequence not present on the X chromosome with *DMY* being the only functional gene. *DMY* is a recently acquired sex determination gene and is not common among fish species. It is present and functions as the male sex determination gene only in medaka and its sister species *Oryzias curvinotus*, and is thus a recently acquired gene. The *DMRT1* gene has been identified and mapped within the genome of several fish species, but so far is not located at same position as the sex-determining region in any fish other then medaka.

Molecular Control of Sex Differentiation

The first signs of sexual dimorphism are typically seen in the gonads. The gonads consist of somatically derived tissues and the germ line. The somatic tissues and germ line are derived from different embryological origins and come together to form the gonad during embryogenesis, typically through migration of the germ cells to the site of the gonad anlage (primordium). Gametogenesis requires the association of the germ line with somatically derived support cells. In the testis, these support cells are the Sertoli cells and in the ovary they are the granulosa cells. The steroid-producing cells of the gonad are also somatically derived. These are the Leydig cells and thecal cells in the testis and ovary, respectively (**see also The Reproductive Organs and Processes**: Anatomy and Histology of Fish Testis).

Sex Differentiation of the Gonad

Sex differentiation in teleost fish is typically divided into two stages. The first being germ line sex differentiation which is characterized by a dichotomy in germ line proliferation and oftentimes the onset of meiosis between the sexes. Somatic sex differentiation follows, which is characterized by seminiferous tubule morphogenesis and efferent duct formation in the testis and formation of follicles and the ovarian cavity in the ovary.

The first sexually dimorphic feature in teleost fish is typically a dichotomy in germ cell number, with females having more germ cells than males. How this dichotomy is established molecularly is not known. In medaka, the sex determination gene, *DMY*, is expressed specifically in male somatic gonadal cells, thought to be Sertoli cell precursors. This expression commences prior to the sex-specific differences in germ cell number. It has been postulated that one of the early roles of *DMY* in testis development is to limit germ cell divisions in males. However, because *DMY* is a transcription factor, it probably regulates gene expression within the Sertoli cells and their precursors. One possibility is that *DMY* regulates the expression of a gene encoding a molecule that signals the germ line to inhibit mitosis.

Somatic sex differentiation is characterized by morphogenesis of somatic gonadal structures. In the testis, somatic sex differentiation consists of formation of the seminiferous tubules and efferent ducts. In the ovaries, it consists of follicle and ovarian cavity formation. During testis sex differentiation, the Sertoli cells enclose the germ line to form the seminiferous tubules. A basement membrane is produced between the Sertoli cells and another somatic cell type called the peritubular myoid cells. Thus, only germ line and Sertoli cells reside within the seminiferous tubules. In the ovary, the granulosa cells surround individual oogonia to form follicles. There is reciprocal dependency on the oocyte and granulosa cells for follicle development. The granulosa cells and oocyte remain intimately associated through cytoplasmic processes that pass through the developing zona pellucida (future eggshell), which forms between the oocyte and granulosa cell layer.

The ovarian granulosa cells and testicular Sertoli cells are thought to be derived from a common precursor cell lineage in the gonadal pirmordium. The common lineage of these two cell types has been demonstrated in mice and medaka. Thus, specification of these two cell types from a common precursor cell population is a critical step in somatic sex differentiation of the gonad.

Genes Involved in Gonadal Sex Differentiation

The molecular mechanisms underlying somatic sex differentiation in fish are as yet not understood. Somatic sex differentiation has been well studied in mammals, leading to the discovery of many genes that function in this process. In recent years, investigators have begun assaying the potential role of genes known to be involved in mammalian sex differentiation in fish, primarily through gene expression analysis. Genes that have been investigated in fish with potential roles in testis differentiation are *SOX9* (Sry related HMG box gene 9), *AMH* (anti-Müllerian hormone/Müllerian inhibiting substance), *DMRT1, SF1* (steroidogenic factor 1, also known as Nr5a1), and *WT1* (Wilms tumor 1). Of these, *SOX9*, *AMH*, and *DMRT1* exhibit sexually dimorphic expression during sex differentiation in at least some fish species suggesting a possible role in this process. In the ovary, two genes have been investigated that have potential roles in ovary sex differentiation: *CYP19A1* (cytochrome P450), which encodes aromatase, and *FOXL2* (**Table 2**).

The *SOX9* gene has been suggested to function in sex determination or gonad sex differentiation in many vertebrates. In mammals, the mammalian sex determination gene *SRY* directly activates *SOX9*. *SOX9* is both necessary and sufficient for male sex determination in both mice and humans. It is thought to drive Sertoli versus granulosa cell fate, thereby controlling testis fate and leading to morphogenesis of the seminiferous tubules. In fish, sexually dimorphic *SOX9* expression does not typically correlate with onset of germ line sex differentiation. However, the sex-specific expression of *SOX9* correlates with the onset of seminiferous tubule formation in several fish species, suggesting that *SOX9* may have a conserved role in this process.

The *AMH* gene often exhibits sex-specific upregulation during sex differentiation of male fish. In the developing testis, *AMH* is expressed in the pre-Sertoli cells and Sertoli cells and remains expressed through adulthood. It is also expressed in ovarian follicle cells of previtellogenic and vitellogenic ovaries. AMH is a secreted glycoprotein of the transforming growth factor beta family (TGFβ) of signaling molecules. In medaka, *AMH* has a clear role in germ cell proliferation and sex determination. Fish with a mutation in the *amh-receptor 2* (*AMHR2*) gene, which encodes for the AMH receptor, exhibit non-sex-specific overproliferation of the germ line, defects in oogenesis, and XY sex reversal (i.e., development of ovaries in a genetically male individual). Thus, in medaka, AMH signaling functions in several processes in gonad development, including testis sex differentiation.

The *DMRT1* gene has been implicated in male-specific development in many animal species. Its role as the medaka sex determination gene has been described previously in this article. Although *DMRT1* has not been implicated as the master sex determination gene in other fish, its expression in the testis oftentimes correlates with the onset of sex differentiation. In some fish, such as the Nile tilapia (*Oreochromis niloticus*), male-specific expression of gonadal *DMRT1* precedes any morphological signs of sex differentiation, including germ line sex differentiation. However, in other species, such as *Oryzias luzonensis*, testicular *DMRT1* expression correlates with the onset of somatic sex differentiation of the testis, but is not expressed earlier during germ line sex differentiation. Thus, *DMRT1* may have a conserved role in sex differentiation of somatic structures and, in some species, a possible additional role in influencing germ line sex differentiation.

Few genes have been investigated during female sex differentiation in fish. Estrogen clearly plays an important role in female sex differentiation (**see also Hormonal**

Table 2 Genes expressed during gonadal sex differentiation

Gene name	*Protein*	*Tissue expressed*	*Expression during sex differentiation*[a]	*Function*
SOX9	HMG transcription factor	Sertoli cells	In developing testes during formation of Seminiferous tubules	Not tested
AMH	Secreted glycoprotein	Sertoli cells	Dimorphic expression prior to somatic sex differentiation in some species Medaka: no dimorphicexpression	Medaka: regulation of germ line proliferation, oogenesis, male sex determination
DMRT1	Zinc finger transcription factor	Sertoli cells some species in germ cells	In developing testis during somatic sex differentiation In some species prior to germ line sex differentiation	Medaka: DMY paralog is the master male sex determination gene
CYP19A1	Aromatase	Granulosa cells Thecal cells	Prior to or at the onset of sex differentiation	Estrogen production
FOXL2	Forkhead transcription factor	Granulosa cells Thecal cells	Prior to or at the onset of sex differentiation	Activates *CYP19A1* expression Tilapia: sex differentiation

[a] The precise expression of the genes listed in this table is variable depending on the fish species.

Control of Reproduction and Growth: Endocrine Control of Sex Differentiation in Fish). The granulosa cells produce the enzyme aromatase, which produces estrogen. Aromatase is encoded by the *CYP19A1* gene. In the ovary, *CYP19A1* expression is often dimorphically expressed during early stages of gonadal sex differentiation suggesting a role of estrogen signaling in ovary sex differentiation. Furthermore, estrogen treatment during the time when sex is determined is typically sufficient to feminize fish, resulting in fully functional females.

The forkhead transcription factor gene, *FOXL2*, has been shown to be an important regulator of ovarian cell fates in mammals. It also exhibits early dimorphic expression and is expressed in the ovarian granulosa cells in several fish species. In fish, it binds to the *CYP19A1* promoter and activates transcription in the ovary. In the Nile tilapia, the function of *FOXL2* has been investigated using transgenic fish expressing a dominant negative form of FOXL2 protein. In these fish, a mutated version of the *FOXL2* gene was introduced that produces a protein that interferes with the function of the wild-type protein, thereby resulting in overall loss or reduced function of the FOXL2 protein. These fish display masculinized gonads in XX fish indicating an important function of *FOXL2* in gonadal sex differentiation in females.

Glossary

Asymptomatic A case in which an animal carries a disease-causing agent but does not show any symptoms associated with the disease.

Bioinformatics The use of information technology in studying molecular biology.

Cytopathic effect An effect where the infecting virus results in a change in the host cell morphology.

Endemic A state in which the pathogen remains within the animal population but only results in disease occasionally.

Exophthalmia The swelling and protrusion of one or both eyes.

Genome All the genetic information for one living organism or virus.

Glycoprotein A molecule which consists of both protein and carbohydrate.

Immunocompromised A state in which the immune system of the animal is unable to fight an infection.

LD_{50} An abbreviation of lethal dose, 50%. This is the amount of a substance (e.g., number of bacteria) required to kill 50% of a given population.

Molecular biology The study of biological molecules including DNA, RNA, proteins, and lipids.

Necrosis Death of living cells and body tissue.

Neutralizing epitope A molecule which, when recognized by the immune system, can effectively neutralize the pathogen.

Pathogen An infectious agent that can cause disease.

Pathogenesis A stage of events that eventually leads to the development of disease caused by a pathogen.

Probiotics Microorganisms which, when applied orally to fish, have a tangible health benefit.

Proteases Enzymes which break down protein.

Proteomics The broad study of proteins and their structures.

Pro-toxins Proteins or compounds, which only become toxins after further modifications (e.g., proteolytic cleavage).

Quorum sensing A form of bacterial cell-to-cell communication, which allows bacteria to control gene expression, particularly with respect to the bacterial population.

Reverse transcriptase An enzyme which transcribes single-stranded RNA to double-stranded DNA.

RNA polymerase An enzyme which produces RNA.

Systemic viremia A condition where the virus has spread throughout the body.

Virion A completely formed virus or viral particle in the infective form.

Virulence A broad term used to describe the ability of an organism to cause disease.

Virulence factor A molecule (e.g., protein) which is involved in establishing disease or maintaining the diseased state.

Virus A small infectious agent which cannot replicate outside the host cell.

Zoonosis Any infectious disease that can be passed from animals to humans.

Introduction

Fish may be exposed to bacterial and viral pathogens, both in the environment and within aquaculture sites. Many of these pathogens can cause significant losses to a wide range of aquatic species and can remain persistent or endemic within populations. Depending on the etiological agent and host, disease symptoms may vary dramatically from overt (see examples of bacterial infections in **Figure 1**) to asymptomatic. Moreover,

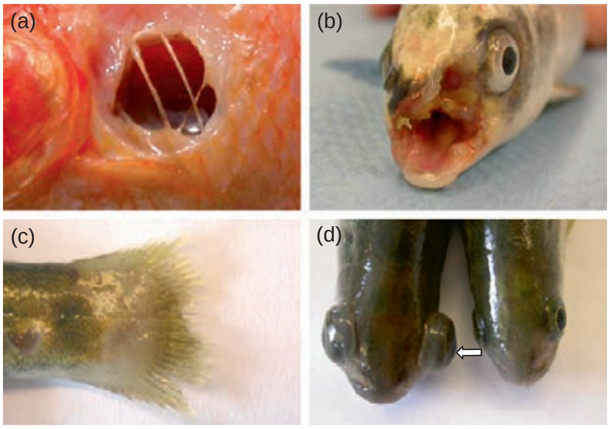

Figure 1 Common symptoms associated with bacterial infections. (a) *Aeromonas salmonicida* infection causing ulceration across the body wall in goldfish. (b) Erosion of ghost carp mouth caused by *Aeromonas bestiarum* infection. (c) Tail rot of a rainbow trout caused by *Aeromonas hydrophila*. (d) Rainbow trout showing signs of a bilateral exophthalmia (indicated by arrow) whereas the fish on the right is a healthy specimen. The etiological agent was identified as *Renibacterium salmoninarum*. Reproduced from Austin B and Austin D (2007) *Bacterial Fish Pathogens: Diseases of Farmed and Wild Fish*, 4th edn. Weilheim: Springer-Praxis Publishing Ltd.

disease symptoms may not be specific for any one pathogen, making diagnosis difficult. Stressed or overcrowded livestock, suboptimal diets, and poor rearing conditions can also contribute to the development of disease. In addition, some fish pathogens (particularly bacterial) can be zoonotic and cause disease in immunocompromised humans. Despite rigorous control measures and immunization strategies, however, there are still significant outbreaks of disease. Nevertheless, advancements in molecular biology and bioinformatics have significantly increased our understanding of fish diseases, pathogenicity, and virulence. This article first gives a general introduction to bacterial fish pathogens and common virulence factors associated with microbes. Attention then turns to viruses, their structures, and life cycles, before covering some topical viruses currently problematic in aquaculture. Finally, current control and preventative measures are discussed, followed by a brief conclusion on the future of molecular fish pathology.

Bacterial Fish Pathogens

Many bacterial species are known to cause disease in fish (some are illustrated in **Table 1**) and often share key features or similarities in the molecular machinery used in establishing an infection (e.g., attachment, invasion, spread, and immune invasion). For example, many bacterial pathogens problematic to aquaculture rely heavily on extracellular products in establishing disease.

Extracellular Products

Extracellular products (ECPs), also known as extracellular enzymes, are secreted by a wide range of bacteria and include amylases, proteases, hemolysins, lipases, and phospholipases. Many ECPs act synergistically to aid colonization, evade host immune systems, kill host cells, and utilize nutrients via the breakdown of macromolecules.

Proteases

Proteases are among the most common components of ECPs. They often aid colonization and provide peptides and amino acids from the breakdown of host proteins. These enzymes have been grouped into four functional classes, that is, the metallo-, serine-, cysteine-, and aspartate proteases. Proteases are produced by many fish pathogens, including *Aeromonas hydrophila*, *A. salmonicida*, *A. jandaei*, *Edwardsiella tarda*, *Yersinia ruckeri*, and *Vibrio vulnificus*. In particular, the metalloproteases and serine proteases contribute significantly to virulence.

Metalloproteases

Y. ruckeri, which causes enteric redmouth disease (ERM) in salmonids, produces a well-characterized metalloprotease. This enzyme is a 47-kDa metallo-endopeptidase belonging to the serralysin family which is secreted via a type I secretion system and is encoded by the *yrp1* (*Yersinia* related protease 1) gene. *Y. ruckeri* strains possessing a mutation in the *yrp1* gene are less virulent *in vivo* compared to their wild-type counterparts. This protease has the ability to break down many host protein substrates including fibrinogen, actin, gelatin, laminin, and myosin. Although this ECP is important for pathogenesis, a number of *Y. ruckeri* strains do not produce it, and are classified as Azo$^+$ or Azo$^-$ depending on their ability to break down azocasein.

Serine proteases

When the serine protease of *A. salmonicida* is purified and injected into fish, it causes liquefaction of muscle tissue, a common pathological sign of furunculosis. This protease is encoded by the *aspA* gene and has a predicted molecular weight of 70 kDa. The enzyme possesses a conserved serine protease binding site, is sensitive to the protease inhibitor phenylmethanesulfonylfluoride (PMSF) and cation chelator ethylenediaminetetraacetic acid (EDTA), and performs optimally in alkaline conditions (pH 9.5) The enzyme may exert an indirect role in pathogenesis by proteolytically cleaving (and thereby activating) excreted pro-toxins.

Table 1 A list of currently topical bacterial fish pathogens

Pathogen	*Disease*	*Host*	*Source*
Gram-positive			
Lactococcus garvieae (formerly *Enterococcus seriolicida*)	Streptococcosis	Many fish species	Australia, Europe, Saudi Arabia, Red Sea, South Africa, Taiwan, and USA
Mycobacterium marinum	Mycobacteriosis (form of fish tuberculosis)	Many fish species	Worldwide
Streptococcus iniae (formerly *S. shiloi*)	Streptococcosis	Freshwater and costal fish	Saudia Arabia, Red Sea, South Africa, Taiwan, and the USA
Streptococcus parauberis	Streptococcosis	Turbot	Spain
Gram-negative			
Aeromonas hydrophila (formerly *A. liquefaciens* and *A. punctata*)	Hemorrhagic septicemia, red sore disease and fin rot.	Many freshwater species	Worldwide
Aeromonas salmonicida subsp. *salmonicida* (formerly *Hemophilus piscium*)	Furunculosis, ulcer disease and carp erythrodermatitis.	Salmonids, cyprinids, and marine species	Worldwide
Edwardsiella ictaluri	Enteric septicemia of catfish	Catfish	Indonesia, USA, and Vietnam
Edwardsiella tarda	Edwardsiellosis and redpest	Freshwater species	Japan, Spain, and USA
Flavobacterium psychrophilum (formerly *Cytophaga psychrophila*)	Cold water disease, necrotic myositis, and rainbow trout fry syndrome	Salmonids and sea lamprey	Australia, Europe, Japan, and North America
Hafnia alvei	Hemorrhagic septicemia	Cherry salmon and rainbow trout	Bulgaria, England, and Spain
Pasteurella skyensis	Pasteurellosis	Atlantic salmon	Scotland
Photobacterium damselae subsp. *piscicida* (formerly *Pasteurella piscicida*)	Vibriosis	Damsel fish, sharks, redbanded sea bream, turbot and yellowtail	Europe and USA
Piscirickettsia salmonis	Coho salmon syndrome and salmonid rickettsial syndrome	Salmon and sea bass	Canada, Chile, Greece, Norway and Scotland
Pseudomonas anguilliseptica	Red spot and winter disease	Rainbow trout, cod, eels, black spot sea bream and gilthead	Finland, France, Japan, Portugal, Scotland and Spain
Serratia liquefaciens	Septicemia	Atlantic salmon, turbot, and charr	France, Scotland and USA
Tenacibacterium maritimum (formerly *Flexibacter maritimus*)	Bacterial stomatitis, gill disease, and necrotic myositis	Many fish species	Europe, Japan, and North America
Vibrio anguillarum	Vibriosis	Most marine fish	Worldwide
Vibrio cholerae (non-O1)	Septicemia	Ayu, goldfish	Australia and Japan
Vibrio harveyi (formerly *V. carchariae* and *V. trachuri*)	Eye disease, necrotizing enteritis and vasculitis	Many fish species	Europe, Japan, Taiwan, and USA
*Vibrio (*now *Aliivibrio) ordalii*	Vibriosis	Most marine fish species	Worldwide
Vibrio salmonicida	Vibriosis (cold water), Hitra disease	Atlantic salmon	Canada, Norway, and Scotland
Vibrio vulnificus	Septicemia and ovate pompano (*Trachinotus ovatus*)	Eel	Europe, Japan, P.R. of China,. and USA
Yersinia ruckeri	Enteric redmouth (ERM) and salmonid blood spot	Salmonids	Australia, Europe, North and South America

Hemolysins/Cytolysins

Iron is an essential factor for pathogenesis and is required by bacteria to grow and proliferate during infection. Although iron is found in abundance within fish, it is often present in protein complexes (=hemoproteins) within host cells. For example, hemoglobin is found within erythrocytes but is not readily accessible for bacteria. Hemolysins are therefore required to lyse cells and release cellular contents, making them available for the pathogen. These enzymes may also lyse other cell types including polymorphonuclear cells, mast cells, and neutrophils. This aids colonization and contributes to virulence and tissue damage. When lysing cells other than erythrocytes, the hemolysins are more commonly known as cytolysins. Although many pathogens produce hemolysins, *Vibrio* spp. and *Aeromonas* spp. produce hemolysins that exert a role in fish and human pathogenesis. *Vibrio* spp. are associated with four different families of hemolysins including the HlyA family, the thermostable direct hemolysin (TDH) family, and the thermostable hemolysin (δ-VPH) family. For some *Aeromonas* spp., however, the hemolysin/cytolysin termed aerolysin plays an important role in virulence and infection (**see also Blood**: Cellular Composition of the Blood and Erythropoiesis in Fishes).

Aerolysin

The conformation of the aerolysin protein, its secretion, and mode of action on host cells have been well characterized. The toxin is initially transported out of the cell as an inactivated protoxin known as proaerolysin. Following secretion, the enzyme is activated by proteolysis of the C-terminal, either by host proteases or by those secreted by the pathogen. Once activated, the protein binds to the eukaryotic host receptor glycophorin where it oligomerizes to form a ring-like structure that creates a pore in the host plasma membrane, eventually leading to permeabilization and cell death.

Lipases

Host cells may be destroyed via the hydrolysis of cytoplasmic membrane phospholipids. In particular, the glycerophospholipid:cholesterol acyltransferase (GCAT), which is produced by *Vibrio* spp. and *Aeromonas* spp., is a highly potent acyltransferase that hydrolyzes many different types of lipids. This lipase is secreted as a pro-toxin and is again activated via proteolytic cleavage. Studies have shown that virulent strains of *A. salmonicida* with a mutation in the serine protease are unable to activate the GCAT pro-toxin *in vivo*. Evidence also indicates that GCAT can contribute to membrane degradation and hemolytic activity alongside aerolysin. The 35-kDa lipase is produced predominately during the stationary phase of growth and acts in conjunction with lipopolysaccharides LPS (GCAT–LPS) to break down phospholipids, including glycerophospholipids and diacylglycerols. GCAT may associate with LPS to prevent proteolytic clearing of the acyltransferase by the host immune system. Injection of the GCAT monomer causes symptoms associated with tissue liquefaction and the formation of furuncles (**Figure 2**). In addition, injecting both the serine protease and GCAT can increase muscle liquefaction. Nevertheless, virulent *A. salmonicida* strains possessing a mutation in the GCAT gene showed no reduction in LD_{50}, suggesting that this lipase/phospholipase may only contribute slightly to virulence.

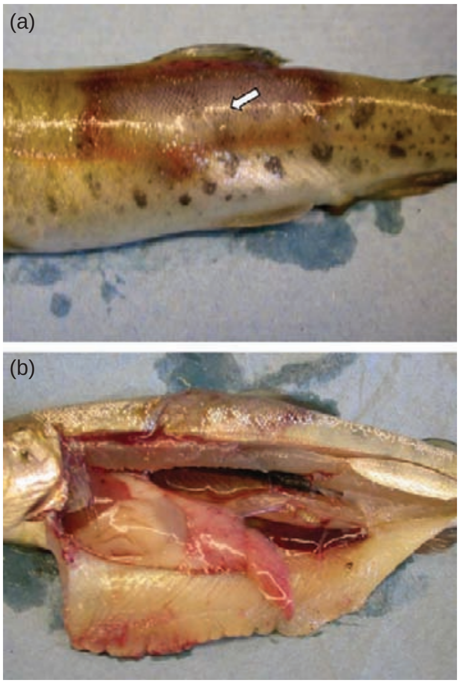

Figure 2 Rainbow trout showing signs associated with a typical *A. hydrophila* infection. (a) Furuncles (indicated by arrow) are swollen areas on the surface of fish and arise from underlying muscle and tissue liquefaction. (b) Exposed internal tissue shows extensive tissue degradation and liquefaction. Photographs: Courtesy of Springer Praxis Ltd and Dr A. Newaj-Fyzul.

Excretion Systems

Before the ECPs can be effective in virulence, they must first be transported across the bacterial outer membrane to the environment or into the fish cell. This is accomplished using large, membrane-bound transport systems, which are often composed of protein complexes. There have been six different types of transport systems identified to date (termed I–VI), although not all are associated with the transport of virulence factors in every organism.

Type I secretion systems (T1SSs) span the inner and outer membrane and are associated with Gram-negative bacteria. This system is important for virulence, in the export of both ECPs and molecules destined for the outer membrane. For example, *P. fluorescens*, which causes a general septicemia for fish, uses the T1SS to transport the adhesion factor LapA to the outer membrane. Type II secretion systems (T2SSs) can also transport ECPs to the environment or host cell cytosol in a two-stage process. Many bacterial fish pathogens use T2SSs for secreting ECPs including some *Aeromonas* spp. and *Vibrio* spp. For example, *A. hydrophila* is able to secrete a wide array of ECPs via T2SSs including a phospholipase, a DNase, a protease, and the well-characterized aerolysin.

Type III secretion systems (T3SSs) deliver proteins directly into the cytosol of host cells and consist of two large protein rings that span the inner and outer membrane. The OMP ring is connected with the large, needle-like structure that extends from the cell's surface to puncture host cells and allow the delivery of effector molecules. T3SSs are thought to aid adherence, invasion, and colonization, and may cause tissue damage, by inducing either apoptosis or necrosis. Mutational studies have shown that *E. tarda*, which causes edwardsiellosis in fish, uses a T3SS in establishing disease.

Type IV secretion systems (T4SSs) span the membrane envelope of Gram-negative bacteria which often possess pili and are involved in conjugation and horizontal gene transfer. This system may therefore enable mobile genetic elements, such as plasmids encoding virulence genes and genes associated with antibiotic resistance, to be transferred between pathogens. A number of fish pathogens use a type VI secretion system (T6SS) to translocate effectors into the host cell including some *Edwardsiella* spp., *A. hydrophila*, and *V. cholerae.* In addition to a T3SS, *E. tarda* contains a gene cluster called *evp*, which is associated with a T6SS. Mutations in these genes attenuated virulence in a gourami fish model, and some proteins encoded by this group of genes have since been studied in detail.

Bacterial Surface Molecules

Lipopolysaccharides

Although ECPs are secreted from the cell, many bacterial fish pathogens can possess toxins which are bound to the outer membrane known as endotoxins. A common class of endotoxin, which is found in *A. salmonicida*, *A. hydrophila*, *V. anguillarum*, *V. vulnificus*, and *E. ictaluri*, is LPS. This endotoxin is found in a number of animal pathogens, including those of higher and lower vertebrates. Although some fish pathogens may possess LPS, they are not endotoxigenic for fish and are merely a component of the outer membrane. LPS has a conserved chemical structure (**Figure 3**) consisting of three regions: a membrane-bound lipid A region, a variable polysaccharide core, and an outer polysaccharide region known as the 'O' antigen. In terms of pathogenicity, the lipid A region is immunogenic and is primarily responsible for elucidating a number of responses in fish. Although a toll-like receptor (TLR)-4 in mammals recognizes the conserved lipid A feature of LPS, the methods of recognition in fish have not been fully established. Nevertheless, recognition of LPS in fish can result in the production of pro-inflammatory cytokines, acute phase proteins (APPs), and antiviral type I interferons. This often leads to the stimulation of other immunological factors such as neutrophils, monocytes, and macrophages. In severe cases, the immune response can be overstimulated by LPS, eventually leading to septic (=endotoxic) shock. However, unlike higher vertebrates, fish are believed to be relatively resistant to this type of shock.

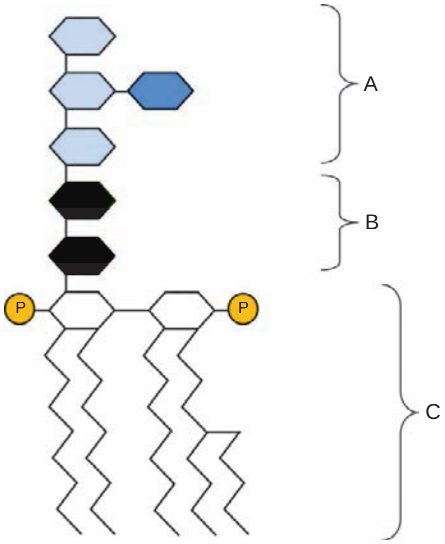

Figure 3 The three conserved structures of LPS. These features include the outer 'O' polysaccharide region (a), a variable polysaccharide core (b), and long-chain fatty acids linked to diglucosamine units which make up the conserved lipid A region(P = phosphate groups) (c). Adapted from Swain P, Nayak SK, Nanda PK, and Dash S (2008) Biological effects of bacterial lipopolysaccharide (endotoxin) in fish: A review. *Fish and Shellfish Immunology* 25: 191–201.

Although in extreme cases endotoxic shock can lead to death, it is more likely to be associated with some physiological effects (e.g., increased respiratory rates, hypotension, and anorexia). However, this may only be an initial response to the LPS toxin (=hyper-responsiveness), with the second exposure stimulating a negligible response. Although a potential virulence factor, administering LPS in low quantities to fish has given cross-protection and enhanced immunity, suggesting that LPS may be a successful immunostimulant in aquaculture. Additionally, LPS may also contribute to bacterial adhesion to host tissue.

S-Layers

The surface layer (S-layer or A-layer) is an important structure for pathogenicity. This flat, paracrystalline surface protein covers the entire outer membrane surface of the pathogen, forming a sheet of tetragonal protein structures. In *A. salmonicida*, the S-layer is composed of large VapA subunits, whereas in *A. hydrophila* the S-layer is composed of a similar protein monomer called AhsA. The *VapA* gene from *A. salmonicida* encodes an ~51-kDa protein with a 21-amino-acid N-terminal sequence which is cleaved once the protein is transported out of the cytoplasmic membrane. This protein sheet is thought to protect the pathogen from multiple factors including phagocytic killing, serum borne factors, bacteriophage, and proteases. It also increases hydrophobicity and association with macrophages. *A. salmonicida* strains, which are unable to produce this S-layer, are subsequently avirulent, whereas VapA^- *A. hydrophila* are only slightly reduced in virulence, suggesting the involvement of other factors. S-layers also aid binding to host cell material (e.g., laminin and fibronectin) which helps maintain the carrier state of the organism.

Attachment and Colonization

There are a number of outer-membrane-associated molecules that aid binding and colonization. In addition to LPS and S-layers, polysaccharide capsules and slime layers (found in both Gram-negative and Gram-positive bacteria) can also facilitate adherence and invasion of host tissue. For example, *Lactococcus garvieae*, which causes a generalized septicemic condition termed 'lactococcosis' in marine and freshwater fish, produces capsules. Capsule-producing strains (termed KG–) were resistant to phagocytosis and more virulent *in vivo* compared to noncapsulated strains (termed KG+). Hence, the presence of a capsule aids attachment and prevents phagocytosis and serum killing.

Similarly, *Streptococcus iniae*, which causes meningoencephalitis in salmonids, possesses a capsule that prevents phagocytosis and attack from factors of the fish innate and humoral immune system. More virulent serotype II isolates of *S. iniae* produce a larger capsule which covers more bacterial surface antigens, thereby providing further protection from phagocytic attack. Serotype II isolates are able to survive within phagocytes, thus providing transport to the central nervous system (CNS) or can cross the blood–brain barrier as free bacteria in the bloodstream. Cells within phagocytes can also induce apoptosis which is thought to facilitate escape from the host cell and prevent inflammation. Although the capsule is important in immune evasion, surface proteins are able to bind trout immunoglobulins via the crystallizable fragment known as the Fc region.

Slime layers may aid *E. tarda* and *Flavobacterium psychrophilum* attachment to host cells. In *F. psychrophilum*, which causes coldwater disease and rainbow trout fry syndrome, slime layers may aid attachment and colonization as pili, fimbriae, or flagellin has not been observed. Pili, such as IV pili, are also used by *V. vulnificus* and *A. salmonicida* to achieve attachment. With regard to *V. vulnificus*, a mutation in the gene encoding a PilD peptidase (*vvpD*) resulted in the loss of pili and extracellular toxin secretion via a T2SS. Although this mutation caused an overall reduction in pathogenicity, it could not be determined if this was due to an absence of pili or loss of ECP excretion. Adhesins, like pili, are also used for adhesion and colonization. *A. hydrophila*, for example, possesses a 43-kDa adhesin termed AHA1 which selectively binds to L-fructose and D-mannose residues present on glycosylated OMPs of host cells. Adhesion mediated via AHA1 is thought to aid epithelial cell invasion.

Flagellin

In addition to being a PAMP, flagellin plays a significant role in motility, adhesion/colonization, and biofilm formation. For instance, *V. vulnificus* mutants possessing mutations in flagellum genes (*flgC* and *flg E*) have reduced motility, cellular adhesion, and cytotoxicity and increased LD_{50} values. Workers have suggested that a reduction in cytotoxicity is primarily due to reduced adhesion to host cells, thereby preventing the delivery of cytotoxins. As flagella can be associated with T3SS, a mutation in flagella genes could inhibit the secretion of toxins associated with this type of transport system, which has been the case for *Yersinia enterocolitica.* Given the rise in nonmotile pathogens (e.g., nonmotile *E. tarda*) causing disease in vaccinated fish, flagellin may be a topical research subject in the coming years.

Regulation of Virulence Factors

The expression of many bacterial virulence factors is regulated by a number of environmental cues, including temperature, pH, and osmolarity. Iron availability, however, is thought to regulate a number of virulence genes for many fish pathogens.

Iron Acquisition

As iron is not readily available for pathogens, measures must be taken to scavenge and sequester iron. For many pathogens, this is usually accomplished using both cellular and extracellular components which aid iron solubilization and transportation across the microbial membrane envelope. For example, *V. anguillarum*, which causes a hemorrhagic septicemia termed 'vibriosis', is able to sequester iron via a number of routes. *V. anguillarum* produces hemolysins/cytolysins which release hemoglobin from the host cell. These molecules can then be recognized on the surface of the pathogen through specific, iron-regulated outer membrane proteins which transports the heme component across the outer membrane and into the cytosol. The receptor protein and transport system is known as the TonB system and is primarily responsible for the utilization of heme from hemoglobin and hemin. In *V. anguillarum*, as with other *Vibrio* spp., two TonB systems (TonB1 and TonB2) function in transporting iron across the cytoplasmic membrane. Although both TonB1 and TonB2 systems transport heme and the siderophore ferrichrome, only TonB2 is involved in transporting the siderophores vanchrobactin, enterobactin, and anguibactin in some *V. anguillarum* strains.

Siderophores are small-molecular-weight proteins which are secreted by the bacterium and have a high affinity for iron. Essentially, these molecules compete with the host for iron and play an important role in establishing disease. For a number of *Vibrio* spp., including *V. anguillarum*, a number of siderophores can be produced. For example, *V. anguillarum* serovar O1 strains possessing a 65-kbp plasmid (pJM1) were 10^7 times more virulent than those in which the plasmid had been lost. Subsequent studies showed that this plasmid encoded genes involved in the transport and biosynthesis of the siderophore anguibactin. Although serovar O2 strains of *V. anguillarum* lack pJM1, and therefore the transport and biosynthesis of anguibactin, they are able to transport the siderophore vanchrobactin. Whereas mutations in either one of the two TonB systems results in reduced virulence, particularly the TonB2 system, double mutants (TonB1$^-$ and TonB2$^-$) are completely avirulent. Given the total lack of virulence when both systems are disrupted, it is clear that the ability to acquire iron is an important feature for pathogenicity.

Quorum Sensing

Although nutrient availability can regulate the expression of genes associated with virulence, bacteria must also control gene expression in response to the bacterial population or cell density. For this to be possible, bacteria must achieve cell-to-cell communication, a feature which is accomplished via quorum sensing. Quorum sensing involves the recognition of small signal molecules which are secreted by the bacterial cell. In particular, Gram-negative bacteria produce acylated homoserine lactones (AHLs) or autoinducers (e.g., AI-2) which are continuously produced by the organism and recognized on the surface of the outer membrane via specific, two-component receptors. Depending on the concentration of AHL or autoinducer, different genes (including those associated with virulence) will be expressed or repressed downstream.

A. salmonicida, *A. hydrophila*, *Vibrio* spp., and *Y. ruckeri* produce AHLs, suggesting a potential role for quorum sensing in regulating pathogenicity. However, not all fish pathogens produce these molecules. Some workers have suggested that gene expression with regard to quorum sensing is related to cell density, whereas others suggest that it is used to determine how quickly degradative proteins would diffuse away from the bacterium. *V. harveyi*, which causes necrotizing enteritis, eye disease, and luminous vibriosis, possesses a well-characterized quorum-sensing system. This organism uses three channels to regulate quorum-sensing-associated gene expression. The first channel is regulated by an acylated homoserine lactone (AHL), called harveyi autoinducer 1 (HAI-1), whereas the second and third channels are regulated by a furanosyl borate diester (AI-2) and cholerae autoinducer 1 (CAI-1), respectively.

For *V. harveyi* a number of virulence-related genes are regulated by this sensing mechanism including an extracellular toxin, a metalloprotease, siderophore production, and proteins associated with a type III secretion system. Studies indicate that the A1-2 and CAI-1 channels are required for virulence in brine shrimp (*Artemia franciscana*), whereas the HAI-1 is not. Therefore, given the importance of quorum sensing for *V. harveyi* and other fish pathogens, studies are now suggesting that this may be a novel target to prevent outbreaks of disease.

Virus Structures

Like bacteria, many different types of viruses are known to infect fish. Unlike bacteria, however, viruses are very small infectious particles (10–400 nm in diameter) which show a great deal of biological diversity. During their extracellular phase, viruses are unable to undergo division or replicate outside the host cell and possess no or few active enzymes. They also lack crucial genetic information required to generate metabolic energy or construct viral components (e.g., proteins). Therefore, viruses are dependent upon host metabolism and are often regarded as 'obligate intracellular parasites'.

Although virion structures are highly variable, they are generally composed of two to three parts including a viral genome (nucleic acid or NA) and a protein coat (capsid or capsule). In addition, some viruses may also have a lipid envelope which contains viral proteins.

Nucleic Acid

The function of viral NA is principally to encode viral enzymes and structural proteins. Unlike the genomes of cells, the composition and size of viral genomes are highly variable and are unique in that they are composed of DNA or RNA. The NA can also be double stranded (dsDNA or dsRNA) or single stranded (ssDNA or ssRNA). The genome may also be split (=segmented) and linear or circularized. For viruses with an ssDNA or RNA genome, strands are said to have a positive ((+) ssDNA or (+) ssRNA) or negative ((–) ssDNA or (–) ssRNA) polarity.

Protein Coat

The protein coat (or capsid) is in close association with viral NA. Both the NA and protein coat, when referred together, are known as the nucleocapsid. The main role of the coat is to maintain stability and protect fragile NA from chemical, physical, or enzymatic damage. The coat can also ensure that NA is effectively administered to the host for replication and may also aid attachment for nonenveloped viruses. Capsids are composed of multiple protein subunits (protomers) which are arranged under two major morphological types: helical and icosahedral.

Helical

This type of symmetry is associated with rod- or filamentous-like virus particles which have a single protomer type stacked around a central axis to form a helical-shaped cylinder. For viruses possessing a helical capsid, the genome is usually (−) ssRNA or (−) ssDNA and is bound to the inner coat via interactions with the positive charges on proteins. The total length of the helical capsid is dependent upon the length of the viral genome. Whereas a number of bacterial and plant viruses (notably the tobacco mosaic virus) lack an envelope, all vertebrate viruses with a helical coat possess a membrane. In addition, all animal viruses have a (−) ssRNA genome and exhibit a high level of similarity in their molecular structure.

Icosahedral

An icosahedron (isomeric) capsid is a regular polyhedron with 20 triangular faces, each one being made up of three protein subunits. Therefore, the smallest icosahedron is made up of 60 subunits (known as the triangulation number or $T = 1$). For the simplest icosahedron of 60 units, all triangular subunits have an identical shape with symmetry around a two-, three- and fivefold axis. Viruses with large genomes, however, require large icosahedral coats which are made up of multiples of 60 units ($T > 1$) and can form many complex shapes and structures.

Envelope

Some viruses, possessing a helical or icosahedral capsid, may have a lipid envelope which is sourced from host membranes. Envelopes can also have viral proteins which span the entire membrane. In this case, the extracellular domain is glycosylated and can have a number of functions including the recognition of host receptors, fusing with the host cytoplasmic membrane or aiding attachment to other virus particles.

Infection

As viruses are unable to replicate during the extracellular phase of the life cycle, the virus must be able to penetrate target host cells, begin viral synthesis, and escape the cell as fully functional virus particles. In general, this complex process can be considered in stages, although the process is often continuous.

Attachment

The initial attachment of a virus to the host cell usually involves the recognition of specific macromolecules (=receptors) present on the surface of the host cytoplasmic membranes. The presence or absence of these specific molecules determines if the target host cell is appropriate for replication of the virus, a feature often referred to as viral host tropism. Host cell receptors can include both proteins, particularly glycoprotein, and polysaccharides present on glycoproteins or glycolipids. Whereas glycoproteins are believed to be relatively specific receptors, carbohydrates are thought to be less specific as many different glycoproteins may share carbohydrate side chains with similar configurations. In some cases, multiple receptors must be recognized by the virus before attachment to the membrane can be achieved. Although many different types of receptors exist, they can be broadly grouped into different classes including membrane-associated receptors, transmembrane transporters/channels, and immunoglobulin-like superfamily molecules.

Penetration and Uncoating

Once bound to the membrane, the virus or viral NA must be transported across the membrane and into the host cytosol before replication can occur. Generally, although some viruses may directly inject viral NA, viral transportation across the membrane can be achieved using three different processes: translocation, endocytosis, and membrane fusion.

Unlike other methods of viral transportation across the membrane, translocation requires energy and involves the transportation of the entire virus across the cytoplasmic membrane and into the cytosol. In this case, the receptor on the cytoplasmic membrane is a transporter which recognizes and binds to the capsid protein of nonenveloped viruses, resulting in the active uptake of the entire virion. Unlike translocation, however, receptor-mediated endocytosis is a common form of viral uptake. This process involves the attachment of viruses on coated membrane pits which then pinch off to form coated vesicles filled with viruses. These vesicles can then fuse with lysosomes after the removal of clathrin, although virion or NA can escape before or after this process depending on the viral type. Both membrane and naked viruses may be taken up by receptor-mediated endocytosis, but again the method of escape from the endosome may vary depending on the virus. Nevertheless, the method of virus uptake by viral fusion is only associated with enveloped viruses. This involves the recognition of viral proteins by host receptors, eventually leading to the fusion of viral envelopes with the host cytoplasmic membrane and the release of the nucleocapsid into the host cytosol.

Regardless of the methods used for penetration, the protein coat must be completely or partially removed before the viral NA is exposed. This process is poorly understood and is thought to vary depending on the virus and nucleocapsid structure, although it may involve the action of viral or host proteases.

Viral Replication

Following the administration of genetic material, the next stage includes the hijacking of cellular processes and the production of functional messenger RNA (mRNA), which is essential for both protein production and genomic replication, with the exception of (+) ssRNA viruses which can be directly translated without further modifications. As viruses differ in the nature of their genetic material, a number of steps must be taken to convert different types of NA to mRNA. Moreover, viruses can be classified depending on mRNA production, a feature known as the Baltimore classification system.

This classification system places viruses under one of several groups (I–VI) depending on the features of mRNA synthesis and the genome. This includes whether the NA is DNA or RNA, single or double stranded, the intracellular location of NA replication, the involvement of a reverse transcriptase, and the polarity (+ or −) of ssRNA. Nevertheless, viruses lack the ability to produce proteins or replicate NA and therefore make use of host amino acids, transfer RNA (tRNA) and ribosomes.

Assembly

Following the replication of NA and production of viral protein, the virus must be assembled before it can be released. The site of viral assembly is dependent upon both the method of NA replication and the method of release from the host cell. Both the structure and assembly of the virus are predetermined, and are usually independent of the formation of covalent bonds. Other methods of interactions, such as protein–protein, protein–NA, and protein–lipid interactions, are important for virus assembly. Once assembled, however, the virus must go through maturation. This is the process by which the virus becomes infectious and usually involves the activity of viral proteases or cellular enzymes, which result in major conformational changes in capsid proteins. Following maturation, the virus may use one of two ways to escape the cell. If the virus is a nonenveloped particle, then it can leave the cell through lysing the cytoplasmic membrane. However, if the virus possesses a lipid envelope then it may escape through budding (**Figure 4**), a process by which the virus effectively obtains the outer membrane as it is released. It is also important to note that other intracellular membranes may be the source of the envelope, including the nucleus, endoplasmic reticulum, and Golgi apparatus.

Fish Viruses

Like bacteria, many fish viruses are known to affect fish in aquaculture and many aspects of virulence have been studied at the molecular level for many different viruses from various families. Some topical viruses, which are currently problematic for aquaculture, are discussed in the following.

Birnaviridae

Infectious pancreatic necrosis virus

Infectious pancreatic necrosis virus (IPNV) has been extensively studied at the molecular level and has been isolated from numerous fish species including salmonids (e.g., Atlantic salmon) and nonsalmonids (e.g., eels, yellowtail, turbot, halibut, and striped bass). Depending on the viral dosage and the age of host, the disease can cause high mortalities and give varying symptoms. In general, the virus causes a disease which is characterized by lesions in the pancreas (particularly for salmonids) and can also include infected kidney macrophage, gut epithelial cells, and liver. An example of the cytopathic effect (CPE) caused by IPNV on infected Chinook salmon embryo cells (CHSE-14) is illustrated in **Figure 5**.

IPNV belongs to the genus *Aquabirnavirus* and is biochemically similar to the *Drosophila* X virus (DXV) and infectious bursal virus (IBDV) of chickens. IPNV is a nonenveloped, spherical icosahedron (60 nm in diameter) (**Figure 6**) which possesses an RNase-resistant dsRNA genome ranging from 2.3 to 3 kb. As the NA is dsRNA,

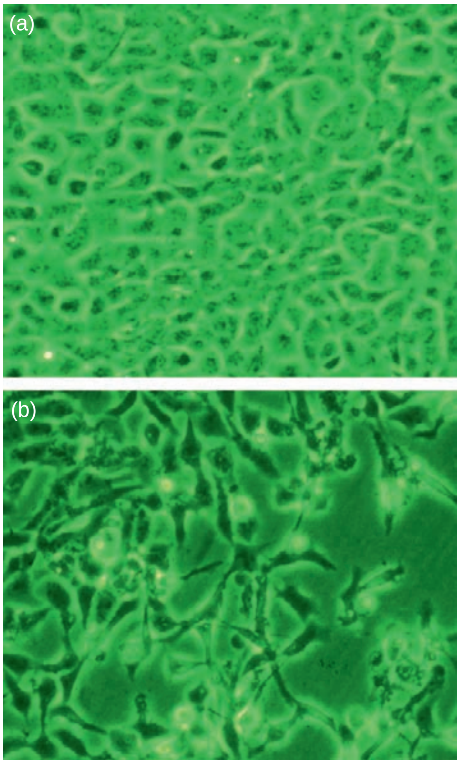

Figure 5 An example of the cytopathic effect (CPE) on cells infected with IPNV. (a) Growth of normal epithelioma papillosum cyprini (EPC cell line) (magnification ×10). (b) CHSE-14 cell line infected with IPNV showing significant changes in cell morphology (magnification ×10).

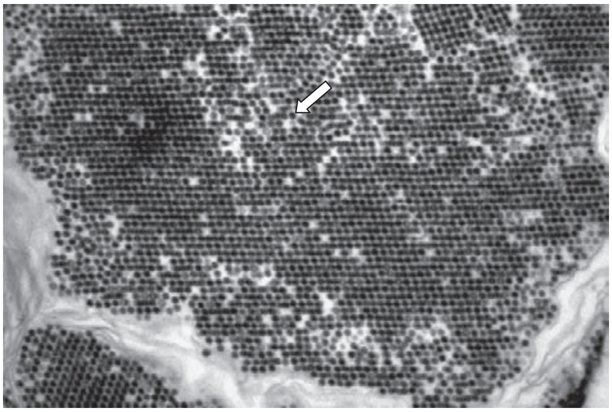

Figure 6 A rotifer cell showing an infection with IPNV. Each spherical object (indicated) represents a single icosahedral IPN virion which forms large virus arrays within the host cell (magnification ×98 000).

members of the Birnaviridae are classified as type III viruses in the Baltimore classification system. The genome is composed of two segments: segment A and segment B, with different strains showing a similar genomic arrangement. Segment A possesses a large open reading frame (ORF) encoding a polyprotein of 106 kDa which is cleaved by viral proteases to produce preVP2 and VP3. VP3 is thought to be an internal capsid protein, although studies suggest that at least part of the molecule is exposed at the surface. The preVP2 undergoes further proteolytic cleavage later in the viral process to give VP2. A second, smaller ORF also exists in segment A, and encodes a small (17 kDa) arginine-rich protein, the function of which remains unknown. Segment B, however, encodes the 94.4-kDa viral RNA-dependent RNA polymerase (RdRp) termed VP1. This protein can exist within two forms; either as a free polypeptide or as a genome-linked protein (Vpg) which is covalently attached to the 5′ regions of RNA.

The infection process is relatively well understood and has been studied both *in vivo* and *in vitro*. Replication occurs primarily at low temperatures and ceases at higher temperatures (>28 °C) when replicated in fathead minnow cells. Following entry into fish via oral or anal routes, the virus attaches to a 100–200-kDa protein receptor present on fish cell membranes via the VP2 capsid protein, resulting in internalization of the virus. However, it is unknown if the virus undergoes uncoating of the capsid as the viral RNA polymerase is still fully functional when the virus is encapsulated. Nevertheless, the genome can be synthesized *in vitro* via VP1-primed, semi-conservative, strand displacement transcription. In this case, VP1 has a dual functioning role, acting both as a primer and as an RNA polymerase to produce plus (+) RNA replicative intermediates. Gene expression, protein synthesis, and the roles of viral proteases (particularly with respect to polyprotein processing) have also been studied.

Orthomyxoviridae

Infectious salmon anemia virus

Infectious salmon anemia virus (ISAV) causes infectious salmon anemia (ISA), a disease which is characterized by exophthalmia, intestinal hemorrhaging, and tubular and liver necrosis, although fish may remain asymptomatic. Infection and transmission occur primarily in seawater, suggesting that the virus infects salmonids during the marine phase of the lifecycle. Horizontal transmission of virus between fish is believed to be primarily through urine and feces, with lice having been implicated as carriers.

ISAV belongs to the genus *Isavirus* and is the only fish virus belonging to the Orthomyxoviridae family. This virus also shares a number of biochemical similarities with the influenza A virus. Although ISAV proteins exhibit relatively low amino acid sequence identity to other members of the Orthomyxoviridae, genomic hybridization with conserved probes confirmed that this virus was correctly placed within this family. Viral particles are enveloped (90–140 nm) and possess a (–) ssRNA genome that is ~14.3 kb in size and composed of eight ssRNA segments. ISAV is classified as a type V virus in the Baltimore classification system.

The virus can survive in seawater for at least 20 h (4 days at 6 °C in blood and kidney tissue) and is sensitive to lipid solvents and low pH. All eight genomic ssRNA sequences have been sequenced and found to encode a putative PB2 and hemagglutinin, whereas expression studies have indicated at least nine structural proteins and one nonstructural protein, which are encoded within the genome.

A well-studied feature of ISAV is the dual-functioning hemagglutinin esterase (HE). This enzyme is a hemagglutinin-binding receptor which aids attachment to host cell material present on the surface of cells, primarily sialic acids (Sias). During attachment, virus particles may incorrectly bind to Sias which are not associated with cells, or with Sias associated with previously infected cells, resulting in a reduction in infection rates. Should this occur then the receptor can act as an esterase (siliate-O-acetyltransferase), otherwise referred to as a receptor-destroying enzyme (RDE), and detach from the bound molecule by acetylating the Sias. Once the virus attaches to the correct Sias, the virus is internalized. Following internalization, the virus envelope fuses with the host endosome membrane and is thought to replicate within host cells in a manner that is not dissimilar to the closely related influenza virus.

Togaviridae

Salmon alphaviruses

Salmon alphaviruses SAVs are known to be pathogenic for salmonids including Atlantic salmon (*Salmo salar* L.) and rainbow trout (*Oncorhynchus mykiss*, Walbaum). A number of virus subtypes (termed SAV 1, 2, and 3) have been associated with a variety of diseases. SAV 1 (salmon pancreas disease virus (SPDV)) and SAV 3 (which is specific to Norway) are associated with salmon pancreatic disease (PD), whereas SAV 2 (sleeping disease virus (SDV)) is linked with sleeping disease (SD).

Based on physical characteristics and genome sequences, the viral agent was placed within the genus *Alphavirus* and Togaviridae family. This spherical, enveloped virus has a (+) ssRNA genome which is 11–12 kb in length and shows relatively high levels of identity between SAV 1 and SAV 2 subtypes. SAVs belong to the type IV class of viruses within the Baltimore system. The genome is composed of two ORFs and encodes five structural and four nonstructural proteins. Structural proteins are encoded within the 3′ region of the genome and include the outer membrane glycoproteins (E2, E3, and E1) and capsid, whereas the 5′ region encodes proteins associated with viral replication (e.g., the viral RNA polymerase). Amino acid identities between SAV 1 and SAV 3 are high for both structural (95%) and nonstructural proteins (93.6%), but relatively low between other SAV strains (30% and 40%). Differences in overall protein structures and posttranslation modifications have also been documented between SAV 1 and SAV 2. Once inside the host cell, the virus can replicate within the cytoplasm and is released via budding through the plasma membrane. This budding process forms the viral envelope that possesses the E1 and E2 glycoproteins which form heterodimers on the membrane surface.

Rhabdoviridae

A number of viruses pathogenic for fish are grouped within the Rhabdoviridae family, including infectious hematopoietic necrosis virus (IHNV), viral hemorrhagic septicemia virus (VHSV), and spring viremia of carp virus (SVCV).

IHNV infects Atlantic salmon in aquaculture, whereas rainbow trout are known to be susceptible in the environment. The disease is characterized by necrosis of the anterior kidney, including necrosis of the hematopoietic kidney tissue and pancreas. However, this disease can be distinguished from VHSV infection in that fish with IHNV show necrosis of the eosinophilic granular cells of the intestinal wall. Infection has been shown to occur through the gills and esophagus epithelium, resulting in a systemic viremia where they spread to the vital organs, causing a necrosis which can often result in death. VHSV (or Egtved virus) is an important viral disease in aquaculture, particularly for salmonids. This virus causes a viral hemorrhagic septicemia (VHS) and is characterized by hemorrhaging in the muscles, eyes, skin, and meninges; necrosis of internal organs (particularly the kidney and liver); exophthalmia; lethargy; and darkening of the skin. SVCV (=*Rhabovirus carpio*) also poses as a threat to carp (particularly *Cyprinus carpio*) and causes numerous symptoms including exophthalmia, skin hemorrhaging, hemorrhagic enteritis, and ascites.

All three members of the Rhabdoviridae discussed earlier are membrane-bound, bullet-shaped viruses (**Figure 7**) which have a nucleocapsid containing a (–) ssRNA genome that is ~11 kb in length. Members of the Rhabdoviridae belong to the type V class of viruses in the Baltimore classification system. The genome is linear and encodes six proteins for IHNV and VHSV, but five proteins for SVCV. Interestingly, the genome composition is somewhat similar for VHSV and IHNV, whereas the SVC genomes vary slightly. As a result, VHSV and IHNV have been re-classified within the genus *Novirhabdoviridiae*, whereas SVC is classified within the genus *Vesiculovirus*. All three genomes, however, encode similar proteins including an outer G protein, an RdRp, a nucleoprotein, a membrane protein which maintains viral shape, and a protein which aids transcription. The G protein, which initiates endocytosis during infection, has been studied

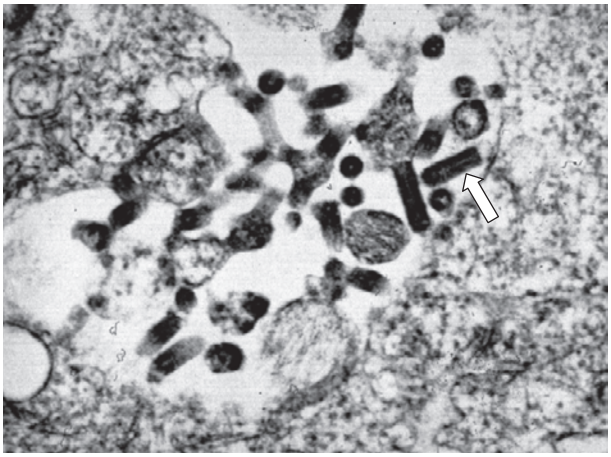

Figure 7 Kidney tissue from Atlantic salmon infected with VHSV. A fully formed, bullet-shaped VHS virion (180 nm in length) is clearly visible (indicated) (magnification ×59 000).

with regard to recombinant vaccine development. Viral replication has also been studied *in vitro*, as has the conditions and mode of spread required for infection.

Orthoretroviridae

Walleye dermal sarcoma virus (WDSV) and walleye epidermal hyperplasia virus 1 and 2 (WEHV1 and WEHV2) are of particular interest not only with regard to fish pathology, but also in understanding oncogenesis and cell proliferation. WDSV causes benign skin lesion in vascularized tumors, whereas WEHV causes a hyperproliferative skin disease which forms plaques of thickened epidermis. Belonging to the retroviruses, these closely related species cause seasonal proliferative skin lesions. For example, during the summer, autumn, and winter seasons, tumors and lesions continue to develop, whereas the level of spliced and unspliced retrovirus RNA remains relatively low. However, during the spring, these lesions regress, but virus replication and infectivity dramatically increase. Studies to date suggest that walleyes do not contract the condition in subsequent years, nor have there been any cases where WDS or WEH has caused mortality.

The genomes of WDSV and WEHV (1 and 2) have been studied at the molecular level. They possess a number of ORFs, including Orf C, B, and A. The WDSV Orf-C protein has been shown to induce apoptosis in cell culture, a factor which may be related to regressing tumors. Both Orf A and Orf B are somewhat similar, with Orf A encoding a retroviral cyclin (rv-cyclin) which shows some identity to cellular C-type and D-type cyclins. Extensive work has been undertaken to try and fully understand the role of rv-cyclin in the viral cycle. Furthermore, WDSV and WEHVs cyclins in walleyes infections may act as a model to fully understand oncogenic properties of cyclins in human cell replication and oncogenesis.

Methods of Control

General control methods for fish pathogens can include movement restrictions (with or without a culling policy), disinfection of ponds and utensils, nonspecific immunostimulants (e.g. β-1,3 glucans), dietary supplements such as vitamins, and the use of genetically disease-resistant stock. In addition, more specific methods (e.g., vaccines) have been developed for both bacterial and viral pathogens.

Bacterial Control

Although antimicrobial compounds (e.g., oxytetracycline) have been used for many years to prevent bacterial disease outbreaks, this is a contentious issue as it allows the development and spread of antibiotic resistance genes. Molecular approaches have been used with some vaccine development, although the bulk of the commercial fish vaccines uses traditional approaches, notably the formalin inactivation of broth cultures. These can be administered by intraperitoneal injection, immersion (the fish are bathed in a diluted preparation), or orally on feed. More modern approaches include the development of DNA vaccines and live, attenuated genetically engineered vaccines (e.g., the aromatic-dependent (*aro*) cells of *A. salmonicida*). However, there is debate over the value of live vaccines because of concerns about reversion to virulence and possible issues with diagnosis, that is, there could be confusion between live vaccine cells and virulent pathogen.

Viral Control

In a similar fashion to bacteria, the development of virus vaccines has been done using attenuated and recombinant vaccines. Subunit vaccines for IPNV produced by recombinant DNA techniques have involved the major capsid protein, VP2, with the gene being cloned and expressed in *Escherichia coli.* Vaccination by intraperitoneal injection and immersion led to the development of antibody. As a component in a multivalent vaccine, VP2 led to a suppression of viral replication in Atlantic salmon following challenge. IHNV has also been another target for recombinant vaccine development. For example, fragments of the G (glycoprotein) genes of IHNV have been cloned into *E. coli.* Plasmid-encoded viral epitopes were then mobilized into an avirulent isolate of *A. salmonicida* A440 for use as a shuttle system for the expression of glycoprotein fragments. This resulted in rainbow trout developing immunity against IHNV. Plasmid vectors encoding viral nucleoprotein or glycoprotein genes under the control of a cytomegalovirus promoter have been used to vaccinate rainbow trout, which received the glycoprotein with or without the nucleoprotein encoding plasmid, produced IHNV-neutralizing antibodies, and were protected against challenge. Protective immunity was transferred from hen fish to fry, which survived challenge. A third example involves VHSV. For this virus, a 2-propiolactone-inactivated preparation and attenuated vaccine were effective in providing protection against this virus in rainbow trout. When applied by intraperitoneal injection, a recombinant baculovirus vaccine was immunogenic and protective, albeit expensive. DNA-based vaccination using VHSV G (glycoprotein) and N (nucleocapsid) proteins, which were cloned individually into an expression plasmid, has been successful. Following injection of G and luciferase genes into rainbow trout muscle, there was a rapid decrease in luciferase activity, indicating that the fish developed a cellular immune response to the antigen. The transfected fish cells were killed, thereby stopping further expression of the G protein and luciferase. Juvenile rainbow trout, which were injected intramuscularly with the G construct, were protected against challenge after 52 days and exhibited viral neutralizing activity within serum.

Conclusions

Aquaculture continues to be hindered by disease despite attempts to understand the molecular basis of fish pathogenicity. However, this field has seen some dramatic breakthroughs within the last 20 years, although some questions still remain unanswered. For example, the methods used by some bacteria (e.g., *Y. ruckeri*) to evade serum killing and survive host defenses are still unclear. Equally, questions still exist over the role of some bacterial macromolecules, such as ECPs (e.g., the metalloproteases of *V. vulnificus*) in causing disease. Furthermore, some processes of viral replication (including uncoating of the viral coat) are still relatively unknown, as are some neutralizing epitopes (e.g., IPNV) which could be used in recombinant vaccine development. Nevertheless, future advancements in NA sequencing, protein sequencing, and *in vivo* analysis will undoubtedly expanded the field of molecular fish pathology.

Glossary

Aromatase Enzyme belonging to the cytochrome P450 family of proteins and plays a key role in the biosynthesis of estrogens through metabolism of androgens such as testosterone.

Green fluorescent protein (GFP) This protein is originally cloned from jellyfish. When it is excited with blue light it exhibits green fluorescence. GFP is one of the most popular reporter proteins in the bio-imaging field because it can be detected without sacrificing cells and organisms.

Hermaphroditism Sexual pattern characterized by individuals that function both as males and females either simultaneously or sequentially.

Medaka A small freshwater teleost fish that lives in temperate zones and, along with zebrafish, is an excellent vertebrate model organism. Its genomic DNA has been fully sequenced.

Nuage An electron-dense cytoplasmic inclusion that is usually observed in association with mitochondria in germ cells. Nuage has been recognized as a marker of a germ-cell line since the early days of germ-cell study. It consists of an aggregation of RNA and proteins that are thought to be essential for the specification of a germ cell. Nuage has been referred to as a germinal-dense body, a nucleolus-like body, and a chromatoid body. Functionally, nuage resembles the pole plasm of an insect and the germ plasm of frogs.

Pluripotent epiblast cell A type of cell derived from an inner cell mass that can differentiate into any cell type except for that comprising extra embryonic tissue. Conversely, a totipotent cell can differentiate into all cell types, including extra embryonic tissue.

Primordial germ cell (PGC) The precursor of a germ cell, which will develop as a gamete; sperm or oocyte. Morphologically, a PGC is distinguished from a somatic cell by its large round shape, large nuclei, and presence of a nuage.

Totipotency The ability to differentiate into all types of cells in an organism.

Trans sex The phenomenon where an individual changes its sex during its lifetime.

Untranslated region (UTR) Messenger RNA (mRNA) contains a coding region, which is translated into protein, and regions that are not translated. If it locates in the 5′ region and 3′ region, it is termed 5′-UTR and 3′-UTR, respectively. Sometimes, 3′-UTR contains regulatory regions, where proteins and micro-RNA bind that can affect mRNA's stability, location, and translation efficiency.

Zebrafish A small freshwater teleost fish that originated from the tropical zone. Zebrafish, as well as medaka, is an excellent model organism for vertebrate development, due to the many kinds of artificial mutants and application of molecular biology techniques.

What Is a Germ Cell?

Among the many kinds of cell lineages, a germ-cell line is the only one that can provide the genetic link between generations and transmit genetic information to the next generation. In this sense, germ cells are an immortal cell line beyond generations, in contrast to a somatic cell lineage, which is destined to die after a fixed number of mitotic divisions, or disappear with the death of the organism.

A germ-cell line contains both male and female gametes, and their precursor cells. In the early stage of development, certain cells are specified as precursors of a germ cell (primordial germ cell (PGC)) and will develop as germ cells. After colonization in a gonad, PGCs differentiate into gametes (sperms or oocytes) by their interaction with the surrounding cells and/or environmental factors.

In most organisms, the specification of germ cells occurs in a specific position distinct from the final position where gonads will form. Thus, during the developmental process, germ cells (or PGCs) migrate to the gonadal anlage.

How Specified Are PGCs?

Germ cells are currently specified in two distinct ways. In many invertebrate and nonmammalian vertebrate species, including fish, cells that inherit asymmetrically localized, maternally provided determinants are specified as a PGC. So far, the determinants of a germ cell are not precisely identified in fish. In zebrafish, however, some maternally supplied materials, including *vasa* and *nanos* transcript, localize at cleavage furrows at the two- and four-cell stages. These materials are thought to be determinants of a germ cell because their removal results in a severe reduction in the number of germ cells.

In mammals, on the other hand, cytoplasmic determinants for germ cells have not been found, but induction signals from neighboring somatic cells before or during early gastrulation are thought to specify PGCs from pluripotent epiblast cells. BMP4 and BMP8b from extra-embryonic ectoderm are thought to be necessary in this process.

Specific Markers for PGCs

In early studies on PGCs in fish, PGCs were identified only by their morphological features because they have features that are distinct from somatic cells. PGCs are round and larger than other cells with large nuclei, and possess prominent nucleoli and a distinct nuclear membrane. Additionally, PGCs contain characteristic inclusions, nuage (also referred to as germinal-dense, nucleolus-like, or chromatoid bodies), which are electron-dense particles that can be observed in cytoplasm with an electron microscope (**Figure 1**). Nuage is often observed in association with mitochondria and is thought to be an aggregate of RNA and proteins. Because nuage is observed in many kinds of germ cells, such as oogonia, oocytes, spermatogonia, and spermatocytes, it is thought that nuage has essential roles in the development and/or maintenance of germline cells.

In *Drosophila*, a special cytoplasm, called pole plasm, is located in the posterior portion of the egg. During embryonic development, the pole plasm is required to establish anterior–posterior patterning and the specification of germ cells. RNA and proteins accumulate at the pole plasm and assemble in polar granules. Thus, nuage in fish shares resembling morphological features and is thought to share the same roles as pole plasm (or polar granules). The RNA molecules *vasa*, encoding an RNA helicase, and *nanos*, encoding zinc finger protein, are the components of polar granules. So far, their homologs have been found in several teleost fish, including zebrafish (*Danio rerio*), medaka (*Oryzias latipes*), goldfish (*Carassius auratus*), rainbow trout (*Oncorhynchus mykiss*), and loach (*Misgurnus anguillicaudatus*). These homologs are found in germ cells in fish. Recently, it has been confirmed that the *vasa* homolog is located in nuage of zebrafish. Thus, *vasa* and *nanos* messenger RNA (mRNA) have been used as germ-cell-specific markers to elucidate the origin and migration route of germ cells in fish.

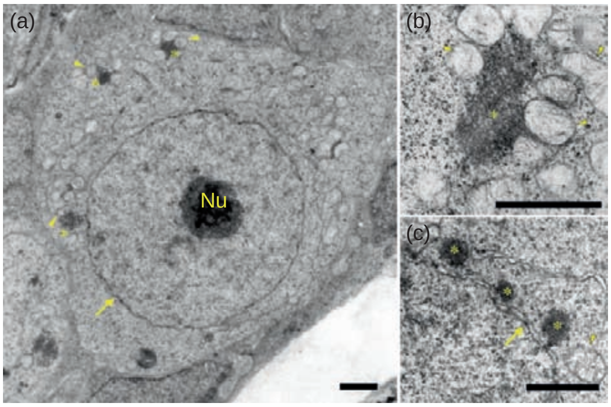

Figure 1 Nuage in medaka PGCs. Nuage is a characteristic inclusion in PGCs. Nuage is an electron-dense particle and is often observed with mitochondria. The asterisk represents nuage, arrowheads indicate mitochondria, arrows indicate nuclear membrane, and Nu indicates nucleolus. Bars represent 1 μm. These figures were kindly provided by Dr. Hamaguchi of Niigata University, Japan.

When Is a PGC Specified?

The utilization of germ-cell-specific molecules, such as *vasa* mRNA and *nanos* mRNA, and recent advances in molecular biology techniques reveal more precise information on the specification of PGCs.

Current knowledge shows that the precise period of PGC specification seems to vary in fish species, and that generally PGCs seem to be specified early in development. In zebrafish, a clump of *vasa* mRNA, a PGC marker, localizes at a cleavage furrow, not in the cytoplasm, until the eight-cell stage. It then localizes in the cytoplasm of four cells at the 32-cell stage, suggesting that at this stage PGCs are specified in zebrafish. The expression pattern of *vasa* in goldfish is identical to that of its confamilial zebrafish (Cyprinidae). In loach (*Misgurnus anguillicaudatus*), the specification pattern resembles that of zebrafish: *vasa* transcript remains at the cleavage furrow until the 32-cell stage and after the 64-cell stage each aggregate of the *vasa* transcript settles into a single blastomere. In contrast to the regional localization of *vasa* transcript in the zebrafish embryo, the transcript in medaka distributes uniformly until late gastrulation. However, using the 3′-untranslated region (3′-UTR) of *nanos*, another PGC-marker, green fluorescent protein (GFP) technology (see below) reveals that GFP-expressing cells scatter around the animal pole at the onset of gastrulation, which is the earliest time point recorded for the detection of PGCs in medaka to date.

PGC Migration

Several methods have been applied to trace PGC migration in a fish embryo. Early morphological observations used light and/or electron microscopy. Once PGC-specific molecular markers, such as *vasa* and *nanos* transcripts, were identified, whole mount *in situ* hybridization used these molecules as probes, making the tracking of the migration route of PGCs easier than morphological analysis. As GFP technology advanced, transgenic fish (**see also Cellular, Molecular, Genomics, and Biomedical Approaches**: Transgenesis and Chromosome Manipulation in Fish and Growth Hormone Overexpression in Transgenic Fish) became subjected to this study. Usually, an artificial DNA construct, in which the GFP gene is placed between the promoter region and the 3′-UTR of the *vasa* gene, is introduced into fertilized eggs by microinjection. In this transgenic fish strain, germ cells, including PGCs, express the GFP gene. Such transgenic strains exist for medaka, rainbow trout, and zebrafish. Another GFP technology that is useful for tracking the migration route of PGCs is the RNA injection technique. The 3′-UTR of *vasa* and *nanos* mRNA involves signals that stabilize RNA and promote translation specifically in PGCs. The introduction of fusion RNA, containing a GFP gene followed by *vasa* or *nanos* 3′-UTR, into fertilized eggs by microinjection leads to the production of GFP, specifically in PGCs (**Figure 2**). With both GFP technologies, PGCs are labeled with green fluorescence and the most advantageous of these technologies is that the movement of PGCs can be traced in living organs in real time using fluorescent microscopy and without sacrificing embryos.

Although the details in the mode of migration of PGCs vary among fish species, a common theme exists for fish investigated to date. After PGCs are specified and segregated from somatic cells, they move to the marginal zone (epiboly stage). Then, PGCs move toward the dorsal midline and align along the lateral mesoderm (gastrula and neurula stage). Finally, the cluster of PGCs moves posteriorly along the body axis and reaches the gonadal primordium, where gonads will form and PGCs give rise to sperms and oocytes. The migration pathway of PGCs

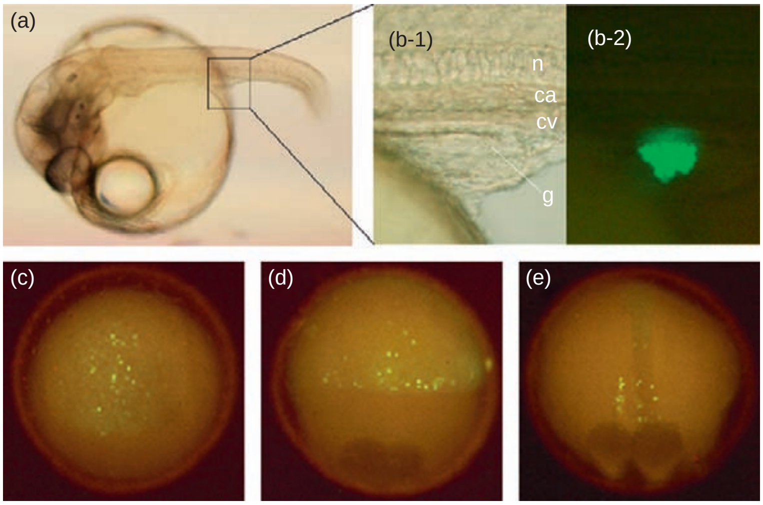

Figure 2 Imaging PGCs with GFP technology. There are two ways to visualize PGCs with GFP technology. One is to establish a transgenic strain that contains a GFP gene regulated by PGC-specific regulatory sequences. The other is the injection of mRNA containing a GFP-coding sequence and PGC-specific UTR. Transgenic medaka harboring an olvas-GFP gene, which contains the GFP gene and a regulatory region of medaka *vasa* gene (a, b). GFP-*nanos* 3′-UTR mRNA-injected embryos (c–e). Usually, mRNA injection enables the identification of PGCs in an earlier stage of embryogenesis. (a, b-1) Normal light images; (b-2, c–e) fluorescent images. (a) Stage 31; (c) animal pole of early gastrula stage corresponding to **Figure 5**(**a**); (d) dorsal view of mid-gastrula stage corresponding to **Figure 5**(**b**); (e) dorsal view of late gastrula stage corresponding to **Figure 5**(**c**). ca, caudal artery; cv, caudal vein; n, notchord; g, gut. (c–e) Modified from Kurokawa H, Aoki Y, Nakamura S, *et al*. (2006) Time-laps analysis reveals different modes of primordial germ cell migration in the medaka *Oryzias latipes. Development Growth Diferentiation* 48: 209–221.

has been relatively well investigated in zebrafish and medaka. In both species, there are two modes of PGC migration. One is passive movement according to somatic cell movement, such as extension and conversion; the other is active migration, as indicated by the following. PGCs migrate in a different direction to the surrounding somatic cells. Although PGCs locate randomly in each embryo, they finally settle together in the gonads. When PGCs migrate, pseudopodia are observed (**Figure 3**). In addition, a guide molecule, stromal cell-derived factor 1 (SDF1), has been found. SDF1 is expressed in somatic cells and indicates the direction where PGCs should migrate. PGCs express CXC chemokine receptor 4 (CXCR4), a receptor of SDF1, and respond to this chemoatractant, SDF1. This signal and receptor (SDF1/CXCR4) system is thought to be a master system of active migration of PGCs, as indicated by the following experiments: the disruption of either SDF1 or CXCR4 disturbs normal PGC migration, and ectopic expression of SDF1 leads PGC to a new SDF1 source. In the following section, recent knowledge obtained from zebrafish and medaka is described.

Kunwar and collaborators have summarized the zebrafish migration pathway and mechanism of PGCs. Once PGCs are specified at the 32-cell stage, mitosis is suppressed and the number of PGCs remains at 4 until the blastula stage (1000-cell stage). PGCs then divide several times and, at the dome stage, four clusters of PGCs randomly locate with respect to the body axes of the embryo. Two of the four clusters locate relatively close to the embryonic body and the other two locate some distance from the embryonic body. The clusters migrate along the embryonic margin toward the dorsal side (**Figure 4**(**a**)). At around 60% of the epibody stage, the cluster that reaches close to the midline then starts to move away from the midline (**Figure 4**(**b**)). Subsequent migration toward the gonadal primordium is active, with movement depending on the SDF1/CXCR4 chemokine system. As shown in **Figure 4**(**c**), the clusters that come close to the midline align at the border between the head and trunk mesoderm, and the other clusters, which come from the ventral part and locate some distance from midline, align at the lateral border of the mesoderm. They then move to an intermediate position, around the first somite of the embryo (**Figure 4**(**d**)). The more anteriorly located clusters migrate posteriorly, whereas posterior clusters migrate anteriorly along the mesoderm (**Figure 4**(**e**)). By 24 h postfertilization, most PGCs are assembled into a single cluster on each side and have reached the region corresponding to the eighth to tenth somites to form two gonads (**Figure 4**(**f**)). At this time, PGCs can be identified morphologically. In addition to SDF1, hydroxymethylglutaryl coenzyme A reductase (HMGCoAR) and Staufen-related proteins (an RNA-binding protein) are thought to influence PGC migration and/or survival.

Both Kurokawa and co-workers and later Saito have summarized the PGC migration and the formation of gonadal primordia for medaka. At the onset of gastrulation (stage 12), about 10 PGCs locate around the animal pole as scattered motile cells (**Figure 5**(**a**)). The active migration of these cells depends on the SDF1/CXCR4 system toward the marginal zone where SDF1 is expressed (stage 15: mid-gastrula stage; **Figure 5**(**b**)). During gastrulation, PGCs extend filopodia and

lamellipodia and move faster than surrounding somatic cells. After staying in the marginal zone for few hours, PGCs migrate toward the midline and align along the lateral plate mesoderm (stage 17: early neurula stage; **Figure 5**(**c**)). In this stage, the PGCs seem to migrate coupled with neighboring somatic cells, and so this mode of movement is thought to be passive and caused by undergoing convergent movement. During migration from the animal pole to the lateral plate mesoderm (from early gastrula to early neurula stage), PGCs proliferate and increase in number to 30–40. As somitogenesis proceeds, PGCs actively migrate posteriorly along the body axis to catch up with the SDF1-expressing domain, depending on the SDF1/CXCR4 system, and arrive at the 11th–13th somite position where gonadal precursors are located (stage 26: 23-somite stage; **Figures 5**(**d**) and **5**(**e**)). Similar to zebrafish, HMGCoAR also seems to be involved in this migration process. In the gonadal primordium-forming process, PGCs approach the gonadal primordium and each PGC is segregated and enveloped by gonadal somatic mesoderm (**Figures 5**(**f**) and **5**(**g**)). PGCs and gonadal somatic cells come from the right and left side of the hindgut, come across at the dorsal side of the hindgut, and form a single gonadal primordium (**Figures 5**(**h**) and **5**(**i**)). Later, this single gonadal primordium divides into the right and left lobes.

Why Do PGCs Migrate?

There is currently no clear explanation as to why PGCs migrate, but it is possible to speculate as follows. During the developmental process, many kinds of cell types specialize and differentiate. This means that many kinds of differentiation-inducing factors are produced and secreted. In order to retain a state of nondifferentiation and totipotency, PGCs should avoid the effects of such factors, and so the cells might be waiting for the differentiation of the somatic gonadal premordium, where they finally settle, and so keep moving until this occurs.

High Plasticity in Sex Determination of Fish

PGCs differentiate into sperms or oocytes once they settle in the gonadal ridge, which develops into the testes or ovaries.

In vertebrates, there are two modes for the determination of sex: genotypic sex determination (GSD) and environmental sex determination (ESD). In GSD, individual sex is determined by whether or not the sex chromosome is inherited. In ESD, the sex of each individual is determined by the local environment, such as temperature.

Mammals and birds follow GSD. In mammals, the sex-determining gene, *sry*, has been identified and the individuals inheriting this gene become male.

In fish, the mode of sex determination depends on the species. Medaka follows GSD and its sex-determining gene, *dmY*/*dmrt1Y*, has been identified. Individuals that inherit *dmY*/*dmrt1Y* become male. In addition to medaka, some fish species have a sex chromosome and follow GSD. However, it is well known that sex differentiation can be altered by the treatment of high or low temperature and by steroid hormones in fish such as medaka, tilapia, salmonid, and flounder. Thus, these fish possess high plasticity in sex determination and differentiation, in contrast to the rigid sex-chromosome determination in mammals and birds. (As for sex determination, **see also Cellular, Molecular, Genomics, and Biomedical Approaches**: Molecular and Chromosomal Aspects of Sex Determination).

What Is a Trans Sex Phenomenon?

In this article, trans sex is defined as the phenomenon where an individual changes its sex during its lifetime. Trans sex has been scarcely observed in terrestrial vertebrates, but in fish it is known to occur in some teleosts, mostly coral fish, but not in the elasmobranchii (**see also Social and Reproductive Behaviors**: Socially Controlled Sex Change in Fishes).

Fish that can change sex are recognized as hermaphrodites. The trans sex phenomenon is caused by switching the functional gonad, from testis to ovary or vice versa. Trans sex in fish is recognized as sequential hermaphroditism and is divided into three types:

1. protogyny, fish that function as a female and later as a male;
2. protandry, fish that function as a male and later as a female; and
3. reciprocal sex change, fish that can change their sex reversibly.

In addition, there is simultaneous hermaphroditism, in which an individual can function as both male and female simultaneously. Fish species belonging to each type are listed in **Table 1**.

Sequential Hermaphroditism

Protogynous fish

This sex change type is common in fish and includes many species. Red porgy (*Pagrus pagrus*) has a bisexual gonad, in which a dorsal ovarian area and a ventral testicular area are separated by connective tissue (delimited type of gonad: **Figure 6**(**a**)). In the female phase, the ovarian part is dominant. As sex change proceeds, mature oocytes and

		Greeneyes	*Chlorophthalmus albatrossis*

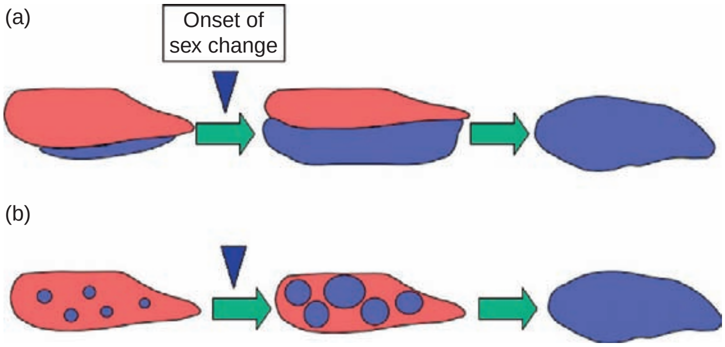

Figure 6 Schematic of two types of gonads observed in sequential hermaphroditism. (a) Delimited type. The ovary and testis are separated by connective tissue. In the first sex phase, a corresponding type of gonad (ovarian or testicular part) is dominant and functional (pink). As sex change proceeds, the dominant gonad part (pink) shrinks and the other gonad part (blue) expands. Finally (second sex phase), the other gonad (blue) becomes dominant and functional. (b) Undelimited type. In the first sex phase, the corresponding type of gonad is dominant and functional. The precursor cells of the other gonad type scatter in the gonad of the first phase. As sex change proceeds, the scattered cells grow and finally (second sex phase) the gonadal tissue has been replaced.

other ovarian cells shrink, and testicular cells, Leydig cells, and spermatogonia expand. Conversely, in wrasse, testicular precursor cells are scattered within the ovary in the female phase (undelimited type of gonad: **Figure 6**(**b**)). After changing to a male, the testicular cells occupy the gonad. However, most protogynous species contain absolutely no testicular tissue in the ovarian tissue in the female sex phase. In the case of Saddleback wrasse, *Thalassoma duperrey*, it takes 3–4 weeks for the gonads to fully change from an ovary to a testis.

Protandrous fish

In black porgy (*Acanthopagrus schlegeli*), gilthead sea bream (*Sparus aurata*), and striped sea bream (*Lithognathus mormyrus*), gonads first differentiate as immature ovaries, followed by the development of bisexual gonads where a testis and immature ovary are separated by connective tissue (delimited-type gonad). Over time, testicular tissue becomes dominant and functional, resulting in an initial male sex phase. In anemonefish, the gonads first differentiate into immature ovaries, and then testicular tissue develops and functions within the immature ovaries without the connective tissue boundary between the two tissue types (undelimited-type gonads). On the other hand, common snook (*Centropomus undecimails*) and giant perch (*Lates calcarifer*) have only testicular tissue in their gonads during the male phase.

Reciprocal sex-change fish

The fish classified in this type usually function as a male or a female, but they have a testis and ovary simultaneously. In the male phase, the testis is mature and functional but the ovary is immature. In the female phase, the ovary is mature and functional but the testis is immature. However, unlike protogynous and protandrous fish, the immature gonadal tissue does not disappear but remains in the gonad. This system enables rapid sex change compared to protogynous and protandrous fish. Actually, in the case of the Okinawa rubble goby, *Trimma okinawae*, it takes only 5 and 10 days to switch the gonad from ovary to testis and vice versa, respectively. Some fish classified in this type are currently first noticed as protogynous or protandrous fish. Therefore, further studies in this area may change the classification of some fish.

Simultaneous Hermaphroditism

Fish in this type have both testicular and ovarian functional gonadal tissues at the same time, meaning that they can release sperm and spawn the eggs any time after maturation. At spawning, a couple trades off between the sperm and the eggs; that is, in the first round of spawning behavior one acts as a male and releases sperm and the other acts as a female and releases the eggs. In the next turn, the previous male acts as a female and vice versa.

When Do Fish Change Sex?

In protogynous and protandrous fish, their sex changes as the fish grow. A model termed the 'size-advantage model' is proposed to explain the advantage of changing sex according to body size. According to this model, changing sex is advantageous at certain body sizes when the rate of reproductive success differs between males and females according to body size (**Figure 7**).

Additionally, some social factors, such as the disappearance of males or females, also induce sex change (**see also Social and Reproductive Behaviors**: Sexual Behavior in Fish). In the case of reciprocal sex-change fish, sex change occurs when two same-sex fish have to live together, such as if the timing that each fish loses its spouse means that an individual of the other sex is not available. In such a case, finding an individual of the opposite sex that is a long way away can be more energetically expensive and can entail a higher survival risk than staying and changing sex.

In any event, changing sex depends on the balance of the cost and benefit, that is, the energy expenditure and overall success of reproduction. In this sense, the trans sex phenomenon has not been observed in elasmobranchii, possibly because their totally differentiated sexual dimorphism with external genitalia for internal fertilization requires too high a cost/energy to rearrange them.

Plasma Steroids Play a Critical Role in Sex Change

In the case of protogynous fish, there is an induced decrease of estrogen (17-β-estradiol (E2)) and/or subsequent increase of androgen (11-ketotestosterone (11-KT))

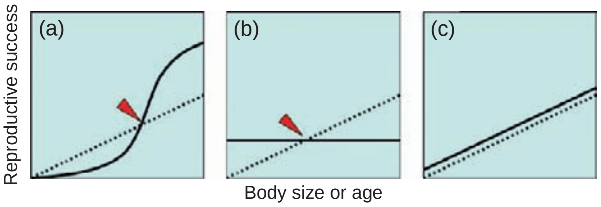

Figure 7 Size-advantage model. Reproductive success generally depends on body size in female fish. Conversely, that of male fish is affected by body size, social system, mating system, and so on. In species where large males monopolize a harem of females, protogyny is advantageous for producing more progeny. Namely, an individual functions as a female with a small body size, then changes its sex to male when it grows to a certain body size (a). Protandry is advantageous in species where small and large males have equal opportunities for mating because small fish can produce more sperms than oocytes (b). In species where males and females are equal in body size, sex change is not advantageous (c). Solid line represents male, and dotted line represents female. Arrowhead represents the time of sex change.

in serum to rearrange an ovary into a testis. Blocking estrogen synthesis with an aromatase inhibitor (AI), such as fadrozole, induces sex change to a male. In the case of protandrous fish, the increase of E2 in plasma induces sex change to female. Additionally, AI or 11-KT treatment suppresses this type of sex change.

The sex change process can be summarized as follows. First, the recognition of the change in body size or circumstance in the nervous system triggers this process and changes the endocrine system. This is followed by an increase in sex steroids that leads to a rearrangement of gonads into the opposite sex.

Glossary

Expressed sequence tag An EST is a short DNA sequence derived from a cloned mRNA representing portions of a gene transcript. The sequence is generally several hundred base pairs from one or both ends of the cloned mRNA.

Hybridization The process of annealing two complementary single-stranded nucleic acids into a single double-stranded molecule.

Hypoxia Low partial pressures of oxygen in external or internal environments.

mRNA An RNA molecule that carries the protein-coding sequence of a gene (CDS) and which is preceded and flanked by a 5′- and a 3′-untranslated region, respectively (5′-UTR and 3′-UTR), which do not contain protein-coding information but which may contain regulatory sequences.

Oligonucleotide A short synthetic nucleotide polymer.

Transcriptome The full set of mRNA molecules (transcripts) produced by the biological system under observation.

Introduction

The physiology of an organism is determined by the combined activities of thousands of genes that are coordinated both temporally and spatially. A central dogma of biology is that genomic DNA is transcribed into messenger RNA (mRNA), which is then translated into protein. This dogma is the foundation behind the study of genomics, transcriptomics, and proteomics, the so-called core 'omics' approaches. Genomics is the study of the genomes of organisms, while transcriptomics and proteomics refer to the study of the complement of mRNA and protein molecules in the organism, respectively. Of these three levels of biological regulation, the study of the regulation of global gene expression at the level of the entire transcriptome has received particular attention.

Why Is Global Gene Expression Measured?

The regulation of mRNA abundance is just one of several levels at which biological regulation occurs and phenotype results from integration at all levels of control. The quantitative relationship between expression of an mRNA molecule and that of its encoded protein is sometimes questioned, since transcript amounts are not always tightly correlated with expression of its encoded protein, and because protein function can be affected through complex post-translational modifications and molecular interactions. The induction of an mRNA transcript is often short term and transient, lasting only long enough for the protein it encodes to be synthesized. Thus, correlations between changes in transcript and ensuing protein levels are likely to be more evident by measurements made during responses to a changed environment or to physiological stimuli rather than in the ensuing steady state. Nevertheless, almost all changes in cell state are accompanied by changes in gene expression, and the regulation of mRNA abundance is an important and perhaps principal means of physiological regulation.

There are two major types of application for which global gene expression data are used. The first aims at identifying individual genes or sets of genes that are differentially expressed across specific conditions or samples. This type of experimental approach is sometimes described as discovery driven or hypothesis generating, which contrasts with more conventional hypothesis-driven approaches in which the expression of specific candidate genes is measured between samples. Examples of this discovery-driven approach would include comparing expression data between groups of fish sampled under different environmental conditions, comparing the transcriptional response of a tolerant versus sensitive fish species, comparing different tissues within the same individual, or comparing transcriptional differences between separate fish species. The overall goal of these applications is to screen a large number of genes so as to identify a subset whose expression is regulated in relation to differences in the phenotypes or genotypes of the samples. Detailed analysis of the functional roles of these differentially expressed genes can provide new insights into the molecular background of the physiological state of the fish.

The second type of application seeks to classify samples according to the gene expression signature they exhibit. This approach works on the assumption that animals of similar physiological state will share similar expressed signatures and that expression data can serve as a surrogate for the physiological state of the fish. In essence, this type of application treats each gene's expression as a phenotypic trait and pattern analysis of hundreds to thousands of these traits allows individuals or samples to be grouped together or separated according to the expression traits they exhibit. An example of this approach would be comparing the transcriptional data of individuals under a range of specific conditions and then grouping the conditions according to the gene expression responses they elicit. This approach makes little or no use of the identity or function of the differentially expressed genes and instead the gene expression signatures serve as a classifier of the physiological state of the individuals under the different conditions.

How Is Global Gene Expression Measured?

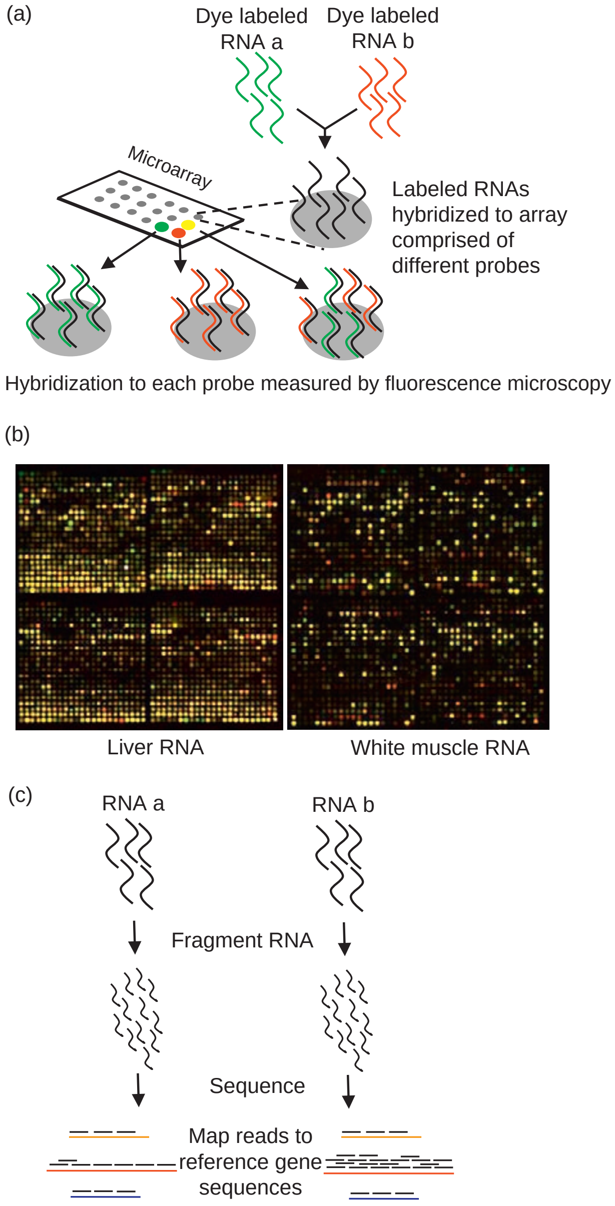
There are two main methods through which global gene expression data can be collected. The first method is hybridization based, in which the RNA molecules in a sample are first labeled with a detectable marker such as a fluorescent dye, and then hybridized to large collection of DNA probes that are bound to a solid phase (**Figures 1(a) and 1(b)**). This arrayed collection of DNA probes is typically called a DNA microarray or a DNA chip. Each probe is specific to a particular gene and the amount of labeled RNA that hybridizes to each probe is a measure of the mRNA abundance of each gene in the sample. While arrays are available for a growing number of fish taxa, it seems unlikely that arrays will become available for every species of fish. To address this shortfall, an approach termed heterologous hybridization can be employed in which RNA from one species is hybridized to an array constructed from probes designed from a different species. The utility of this approach depends on the degree to which nucleotide sequence differences between the species affect the kinetics of the nucleic acid hybridization at each arrayed probe. This approach is likely to be most successful between phylogenetically related species, but nevertheless differences in the rate of gene sequence evolution may mean that certain genes will hybridize to the array better than others leading to false assumptions regarding gene abundance.

The second expression profiling method uses high-throughput sequencing to directly sequence the population of RNA molecules within a sample, with mRNA abundance measured by the frequency with which the sequence of a specific gene is detected within the sequencing data (**Figure 1(c)**). This approach is sometimes referred to as whole transcriptome, shotgun sequencing, RNA sequencing, or RNA-Seq. Until recently, hybridization-based approaches were the main method by which gene expression data were collected, but recent innovations in sequencing technology and reductions in cost may mean that sequencing-based methods will dominate in the future. Either way, both methods can measure the mRNA abundance for almost every gene in the transcriptome, offering a global perspective on the role of the gene expression in the physiology of an animal.

The implementation of either method requires that pre-existing sequence data are available in the form of either genomic or gene transcript sequence. Transcript sequences can be produced by sequencing mRNAs that are cloned as cDNA copies. The resulting sequences are often referred to as an expressed sequence tags (ESTs), and represent single sequence reads from one end of cloned mRNAs. Microarrays are fabricated using either polymerase chain reaction (PCR) products or oligonucleotides as probes, and are termed cDNA or amplicon arrays, or oligonucleotide or oligo arrays, respectively. Probes derived from PCR products are generated by targeted amplification of specific genes based on their DNA sequence, or by amplification of cloned mRNAs. When oligonucleotides are used as probes, the sequences of the arrayed oligonucleotides are designed to match specific parts of the gene transcript. The need for pre-existing sequence data is reduced with RNA sequencing approaches because the sequencing effort itself is capable of producing complete gene sequences. Nevertheless, a reference set of gene sequences is required so that the resulting RNA sequences can be mapped to specific genes, the gene expression being a function of the number of sequences from that gene discovered in the transcriptome, relative to the length of the gene.

Sources of Variation in Gene Expression Data

The major sources of variation in gene expression screens are attributed to environmental and biological factors. Transcript levels are responsive to a wide variety of



(a)

Fragment RNA
Sequence
Map reads to reference gene sequences

Figure 1 Schematic depiction of the two major global gene expression profiling methods. (a) A microarray of arrayed DNA probes is hybridized with either one of two target RNA samples that are labeled with different dyes. The amount of target RNA that hybridizes to each DNA probe is determined using a fluorescence scanner and is a measure of the abundance of that mRNA in the sample. (b) Examples of fluorescent images of a carp microarray hybridized with RNA isolated from liver or white muscle tissue. Note that the fluorescent intensity for each spot is different between the two tissues and is a measure of differences in mRNA abundance between the tissues. (c) In RNA sequencing the sample RNA is fragmented and the fragments sequenced to great depth. The resulting sequences are aligned with and mapped to reference gene sequences. Relative abundance of a transcript is a function of how many sequence fragments derived from the gene were discovered relative to the length of the gene. The red gene is relatively more abundant in RNA b.

environmental variables and so variation due to these factors can be reduced by careful experimental design that excludes unwanted sources of variation. Particularly important variables are temperature, oxygen, salinity, photoperiod, and diet. Experiments are best conducted with fish that have been housed for a period of time under common-gardened conditions where all these variables are carefully controlled and standardized across experimental treatments. Gene expression studies in mammals indicate that the circadian rhythm has a potent effect on global gene expression levels and so the time of day at which samples are taken should be standardized. Efforts to interpret transcriptional differences between individuals sampled in their native habitat are always confounded due to the myriad of environmental differences that might exist between any two habitats. Variation at the measurement level does exist but can be controlled to an extent by technical replication and statistical methods.

A major source of biological variation is related to genetic differences between individuals. With the exception of highly inbred lines of fish, most fishes will differ to some extent at the genetic level. There is an established association between sequence variation and gene expression variation. Indeed, variation in transcript abundance between individuals is a heritable trait and provides the principal means by which genetic differences have their phenotypic effect. In the Atlantic killifish, *Fundulus heterclitus*, analysis of inter-individual variation in metabolic gene expression in the brain, heart, and liver reports that >50% of genes exhibit statistically significant differences in transcript abundance across individuals. This variation appears to be meaningful and differences in cardiac metabolism in killifish are correlated with changes in cardiac gene expression. Individuals with similar cardiac metabolism are also similar with respect to the relative abundance of metabolic genes that they are expressing. While correlation is different from causality, it suggests that patterns of gene expression can explain metabolic variation and in turn can be used to classify individuals according to physiological state.

Another important source of biological variation is behavioral. In Nile tilapia (*Oreochromis niloticus*) populations, males can be socially dominant or subordinate, or reproductively active or suppressed, and different brain gene expression patterns are observed in fish displaying each of these behavioral types. Behavioral differences such as these are observed in many fish species, and because these behaviors are reversible, brain gene expression patterns may be extremely plastic changing in accordance with the behavior currently displayed by the individual. Gene expression differences also play an important role in future behavioral traits. Sedentary versus migratory populations of brown trout, *Salmo trutta*, exhibit profound differences in liver gene expression long before the process of migration is initiated. Fish that are destined to migrate out of streams display a particular pattern of gene expression, which indicates that this behavior is preprogrammed, and, furthermore, this expression pattern is detected in all populations that migrate. Thus, behavior patterns displayed in either the present or future are manifest as gene expression differences.

Physiological Insights Arising from Global Gene Expression Data

Insights into Environmental Acclimation and Adaptation

Fish are a diversified vertebrate family and are found in almost every aquatic habitat on Earth. Their occurrence in a wide range of environmental habitats is a testament to the diversity of their physiologies and their capacity to adapt to different environmental conditions. The ability of an organism to change its phenotype in response to changes in the environment is termed phenotypic plasticity. Phenotypic plasticity is achieved through a process termed acclimatization or acclimation, in which an organism adjusts its physiology to suit the prevailing environmental conditions. Acclimatization refers to this process in field settings where many environmental variables are changed, while acclimation refers to the process when it is studied in the laboratory and the changing variables are carefully controlled. In both instances, this process occurs over a short time and within the lifetime of the organism. This has made fish favored subjects for analysis of the mechanisms underlying phenotypic plasticity. In contrast, evolutionary adaptation is brought about by the accumulation of genetic changes that enhance fitness of the species in the context of its environment. The resulting adaptations are traits upon which natural selection has acted to improve or maintain their function adequate to the particular environment. Most adaptive changes are accomplished either by changes in the temporal, spatial, or quantitative expression of a gene, or alternatively by changes in the function of the encoded protein. These genetic modifications occur through either sequence changes in the regulatory or coding regions of a gene, respectively.

A phenotype results from an interaction between genes and the environment, and so monitoring global gene expression changes has become a standard approach for understanding the molecular basis for alterations in physiological state and phenotype. These gene expression screens have the potential to identify specific genes, pathways, or classes of genes whose expression is actively regulated during environmental change. The addition of temporal (when they are expressed) and spatial information (in which tissues they are expressed) regarding the expression of these genes provides insights into the coordination of phenotypic plasticity and the role of the different organ systems in bringing about physiological change at the level of the whole organism. The two environmental variables that affect all fish regardless of habitat are temperature and oxygen availability.

Temperature

The majority of fish are poikilothermic and their body temperature matches that of their environment. This makes temperature one of, if not the most important, environmental variables with which fish must contend. This is especially true of temperate fishes that typically experience annual temperature ranges from 2 °C to greater than 30 °C. Most temperate fish exhibit phenotypic plasticity over this temperature range by adopting compensatory strategies that serve to maintain physiological performance at relatively constant levels despite the acute rate effects of temperature on all biochemical processes. These compensatory responses are associated with profound changes in global gene expression in fishes.

A survey of the transcriptional changes that occur in seven tissues of common carp, *Cyprinus carpio*, as function of time, and three different extents of cooling, reveals that >50% of genes in the transcriptome are differentially expressed during cold acclimation (**Figure 2**). All tissues respond to cold with a common transcriptional response that comprises genes involved in preserving energy charge, protein turnover, nucleic acid binding, and cell stress. The vast majority (>95%) of the genes that make up this common response increases in expression upon cooling, reflecting a basic paradigm of cold acclimation that organisms frequently compensate for the rate-depressing effects of cold by synthesizing more enzymes to increase biochemical performance. Generally, it appears that gene induction is a graded function of the thermal perturbation, and is transient with transcript levels falling after several weeks at the respective colder acclimation temperatures. The brain is the most active tissue with respect to gene expression changes, particularly with respect to genes linked to cholesterol, fatty acid, and sterol metabolism, consistent with the importance of lipids for proper function of the central nervous system. In most carp tissues, genes involved in the tricarboxylic acid cycle are consistent with other studies that have shown that mitochondrial enzyme activities are elevated in cold-adapted fish populations. Similarly, genes involved in protein translation initiation and protein folding are upregulated consistent with evidence from prokaryotes that suggests that cold compromises the translational apparatus.

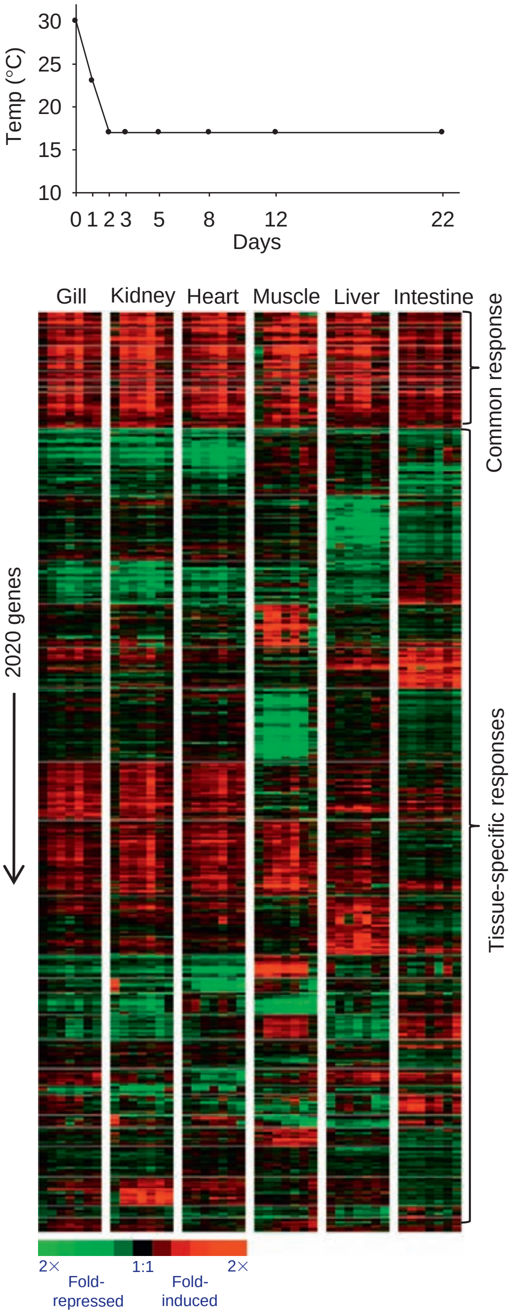

Figure 2 Global gene expression profile of 2020 genes in tissues of cooled carp. Each row represents a different gene and each column represents the expression of the corresponding transcript in carp tissues at 1-, 2-, 3-, 5-, 8-, 12-, and 22-day time points during cold acclimation from 30 to 17 °C. The expression of each gene is presented as the ratio of transcript abundance in each cooled sample relative to its mean abundance in the control 30 °C acclimated fish. Red color indicates a relative increase in transcript abundance with cooling, and green represents a decrease.

Over evolutionary timescales, species can offset the rate effects of temperature by evolving enzymes that are tailored to perform optimally at the typical habitat temperature of the species. While this appears to be a universal strategy, comparison of transcriptomes across taxa offers insights into the role of differential gene expression in the process of evolutionary adaptation. Relative to temperate species, the transcriptome of a cold-adapted Antarctic notothenioid, *Dissostichus mawsoni,* exhibits a preponderance of elevated genes. The functional roles of these elevated genes are very similar to those of the classes of genes that are induced in cold-acclimating carp, such processes as protein degradation, lipid transport, molecular chaperones, and reactive oxygen species scavengers. The concordance between gene expression patterns over both evolutionary and acclimatory timescales indicates the central role that elevating gene expression plays as a mechanism to offset the rate-depressing effects of cold. It also suggests that studying the mechanisms that underpin environmental acclimation provides insights into the processes that underpin evolutionary adaptation to a particular environmental parameter.

Environmental evolutionary adaptation also occurs at a local level when barriers exist that restrict mating and gene flow between populations. Local adaptation is the evolution of traits that confer enhanced fitness to a particular population in a local environment. When comparing the transcriptomes of genetically distinct populations of Atlantic killifish whose range is distributed along a latitudinal thermal gradient of 8–19 °C, the expression of

18% of metabolic genes correlates with local habitat temperature. Interpreting these data within the context of the genetic relatedness of the populations suggests that the expression level of 22% of the habitat temperature-correlated genes is explained by natural selection. The majority of genes whose expression is affected by natural selection are orthologs of genes that are induced in cold-acclimating carp providing further evidence that similar physiological strategies regulated by differential gene expression are employed to deal with cold over both immediate and evolutionary timescales.

Oxygen

Dissolved oxygen levels can fluctuate in aquatic habitats due to a variety of factors. Limitation in availability of oxygen (hypoxia) is a debilitating stress and leads to rapid adaptive changes in ventilator physiology coupled to changes in metabolic organization. Differential gene expression is central to this metabolic response and is mediated in part by the transcription factor, hypoxia-inducible factor 1α, which increases the downstream expression of a suite of genes that enhance anaerobic metabolism and delivery of oxygen to tissues. While much is known about the hypoxia molecular response in mammals because of its relevance in biomedicine, relatively little is known about the response in fish, which in contrast to mammals exhibit a far greater tolerance to protracted periods of hypoxia. When challenged with hypoxia, the long-jaw mudsucker goby, *Gillichthys mirabilis*, alters gene expression so as to reduce the major energy-demanding processes such as contractile protein synthesis and cell division in muscle, while in the liver genes associated with anaerobic glycolysis and gluconeogenesis are elevated. Notably, very few genes exhibit differential expression in brain. During hypoxic stress, the brain is likely to receive a preferential supply of oxygen and glucose, so alterations in gene expression may be minimal relative to tissues such as skeletal muscle that undergo substantial decreases in activity. Similar expression patterns are observed in long-term hypoxia-acclimated zebrafish, *Danio rerio*. In zebrafish gill, genes associated with oxidative phosphorylation and protein synthesis are reduced, while glycolytic genes responsible for generating adenosine triphosphate (ATP) in the absence of oxygen are elevated. The apparent reduction in energy-demanding processes in these two divergent taxa suggests that this might be a common response to hypoxia in fish and may provide a common mechanism that allows diverse fish taxa to acclimate successfully to a reduced level of oxygen.

In common carp, a gene expression screen for hypoxia-regulated genes across multiple tissues reveals that myoglobin, an intra-cellular oxygen-binding protein, is expressed in tissues other than skeletal and cardiac muscle. Specifically, hypoxia exposure is associated with elevated expression of myoglobin in liver, gill, and brain tissue. The detection of myoglobin in nonmuscle tissues is an unprecedented finding, and suggests that myoglobin may play a previously undocumented role in the hypoxic response of fish. This discovery exemplifies the power of global gene expression screens in revealing unexpected physiological responses. It is also a reminder that assumptions regarding the functional role of specific genes may need to be revised when they are investigated within the context of the environmental responses of fish.

Glossary

Bioaccumulation	The process by which substances accumulate in the tissues of living organisms from all sources in the environment.
Bioconcentration	The accumulation of chemicals or metals in living organisms to higher concentrations than in environment from water.
Biomagnification	Increase in concentration of chemicals or metals through the food chain to highest levels in highest trophic level.
Contaminant	Any substance that enters a system where it is not normally found.
Dose	Amount of chemical absorbed, usually per unit weight.
Dose–response	The relationship between the amount of chemical absorbed and the effects observed.
Essential metal	A metal that has a defined biological role.
Heavy metal	A metal of relatively high density (specific gravity greater than about 5) or of high relative atomic weight.
Metallochaperone	Any of a family of proteins that move metal ions to specific sites within a cell.
Metallothionein	A small protein that a group of cysteine-rich proteins with an ability to bind heavy metals.
Nonessential metal	A metal which does not have a known biological role.
Pollutant	Contaminant that adversely alters properties of the environment.
Toxicodynamics	The process of interaction of chemical substances with target sites leading to adverse effects.
Toxicokinetics	Processes of the uptake of potentially toxic substances, biotransformation, distribution, and elimination.
Xenobiotic	Chemicals that are foreign to a biological system.

How Do We Classify Metals?

In the periodic table (**Figure 1**), metalloids occur along the diagonal line through the p block from boron to astatine. Elements in the upper right of this line display increasing nonmetallic behavior; elements in the lower left display increasing metallic behavior.

Metals can be categorized as biologically essential and nonessential; nonessential metals (e.g., tin (Sn), aluminum (Al), cadmium (Cd), mercury (Hg), and lead (Pb)) have no demonstrated biological function (also called xenobiotics or foreign elements). The toxicity of nonessential metals rises with increasing concentration (**Figure 2**). Essential metals (e.g., copper (Cu), zinc (Zn), and iron (Fe)) are

Figure 1 Periodic table of the elements showing various metals and elements with metallic properties (metalloids).

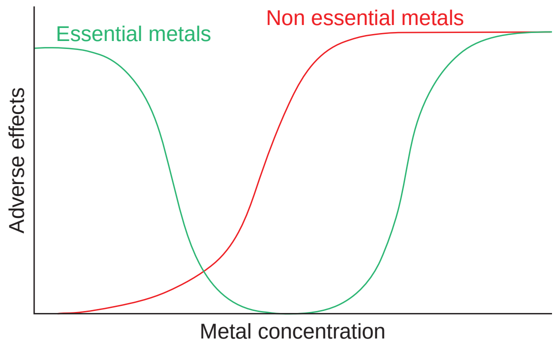

Figure 2 The concentration-adverse-response curves for essential and nonessential metals. Essential metal deficiency leads to adverse health effects as does high concentrations. Nonessential metals are toxic at low concentrations, and exhibit a typical toxicological concentration-response curve.

those with a functional biologic role. Thus, a deficiency of an essential metal causes an adverse health effect, whereas high concentrations can result in toxic effects that are equivalent to or worse than those caused by nonessential metals (**Figure 2**).

Metals are also commonly categorized as either light or heavy (typically greater than 50-Da molecular weight) metals (HMs). A further classification scheme of HMs considers both essentiality and toxicity: Class A HMs include Fe, which is essential in relatively high concentrations. Class B HMs have no established biological role and, at low concentrations, exhibit little or no toxicity (e.g., lanthanum and strontium). Class C HMs include essential metals, but are very toxic at higher concentrations (e.g., Zn, Cu, nickel (Ni), cobalt (Co), molybdenum (Mo), and chromium (Cr)). Class D HMs are toxic at even very low concentrations, and have no clear biological function (e.g., Hg, Pb, Cd, Sn, and uranium (U)).

Environmental Fate and Bioavailability of Metals

Most released metals enter the aquatic environment as a result of direct input, atmospheric deposition, and erosion due to precipitation. Distribution in water is determined by the physico-chemical properties of the metal and is influenced by complex and diverse environmental parameters including dissolved organics, pH, salinity, hardness, and sedimentary load.

Soluble metals include simple dissolved metal ions, metal ion complexes with organic ligands and with inorganic anions. For dissolved metals, there is considerable evidence that the dissolved ionic form is the major bioavailable form and correlates best with metal toxicity. Bioavailability refers to the proportion of metal that can be absorbed by the organism in relation to the total amount of metal in the environment. The bioavailable fraction is accessible to the epithelial surfaces of the animal and can either diffuse or be transported into the cells. Metals can also be found in organic forms as bioavailable organometallic compounds (e.g., organomercurials and organotins (**Figure 3**)). Metals sorbed onto suspended mineral and organic particles are in particulate forms, and the relative importance of these complexes to metal toxicity is still unclear.

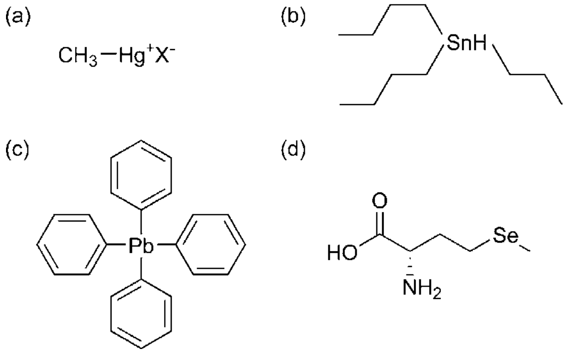

Figure 3 Several examples of organometals: (a) methyl mercury, (b) tributyl tin, (c) tetraethyl lead, and (d) selenomethionine.

Biological Fate and Toxicokinetics

Metal toxicity is dependent on its absorption, distribution, metabolism, and excretion, collectively termed ‘toxicokinetics’. HMs accumulate in the tissues of aquatic animals and become toxic when concentrations reach toxicity thresholds, values that vary considerably between metals, metal species, and taxonomic species and organism life stage.

Absorption

The major sites of metal uptake in fish are the gills, digestive system, and, to a lesser extent, the integument. Metal bioavailability is influenced by chemical speciation and complexation in the environmental matrix. The soluble ionic form is believed to be the bioavailable fraction, that is, the form that is absorbed; therefore, the free metal ion concentration rather than the total metal concentration in the environmental matrix is the major determinant of metal toxicity.

There are two main processes for metal uptake: membrane protein transporters/channels (i.e., carrier mediated, not active transport) and passive diffusion. Metals can move into cells simultaneously via several separate and parallel transport mechanisms. For example, Cu uptake in gills can occur through both Na-sensitive (via epithelial Na channels (ENaC)) and Na-insensitive (via putative high-affinity Cu transporter (Ctr) family of proteins) pathways.

The valence of metal ions (free metals) and their propensity to bind to organic material limits their ability to traverse cell membranes without interacting with membrane protein constituents. For class A–C HMs, these mechanisms include both transporter proteins (e.g., Fe^{2+}/H^+ symporter (divalent metal transporter 1) or the zinc transporter-1) and channels (e.g., the epithelial calcium channel and the ENaC) (**Figure 4**). No such mechanisms have evolved for class D HMs (e.g., Cd); therefore, they are assumed to take advantage of these essential transport mechanisms. Metal uptake can be enhanced by the maintenance of metal concentration gradients through binding to intracellular ligands (e.g., metallochaperones (MCs), metallothioneins (MTs), or metal-binding proteins), as well as their efflux (e.g., via ATPases or exocytosis) across basolateral membranes (**Figure 4**).

Lipophilic molecules can passively diffuse through cell membranes, and several lipophilic metal compounds move into fish via this route. Metals can form neutrally charged chloro-complexes (e.g., $HgCl_2$ and $CdCl_2$), and complexation with various hydrophobic ligands, such as xanthates, diethyldithiocarbamates, and dithiophosphates, can increase their lipophilic characteristics. Some metals can exist as lipophilic organometallic compounds (e.g., organomercurials, organotins, and organoselenium) as well.

Distribution, Storage, and Sequestration

Metals such as copper do not exist as free ions in the intracellular milieu (intracellular free Cu concentrations are believed to be 10^{-18} M) due to binding to various chelation sites. For example, MCs are soluble, cytosolic intracellular trafficking proteins that deliver metal ions to specific target proteins (e.g., Atx1 in a Cu secretory pathway). These trafficking proteins are not detoxification proteins; they simply guide and protect the metal ion while facilitating appropriate partnerships (**Figure 4**).

MTs are ubiquitous low-molecular-weight proteins rich in cysteines with a high affinity for specific metals. They function in metal homeostasis by binding essential metals and in defense by sequestering nonessential metals. MTs have been identified in most tissues, including the blood, and can be induced in tissues that are active in metal uptake, storage, and excretion (**Figure 4**). The induction of MTs may not only increase the tolerance of fish to metals, but also decrease metal excretion rates due to sequestration; ecologically, this may increase the potential for bioconcentration within a fish and transfer through a trophic food chain.

Extracellular transport of metals occurs via the circulatory system by diverse plasma proteins. Protein-mediated transport can be either specific (e.g., Fe by transferrin) or nonspecific (e.g., Ni by serum albumin) or both (**Figure 4**).

Biotransformation

Biotransformation is strictly defined as the enzymatic conversion of xenobiotics into more water-soluble metabolites in order to enhance excretion. This definition does not apply to metal ions; however, enzymes can alter their redox state (e.g., membrane-bound cupric reductases; **Figure 4**) and metal toxicokinetics. Organometals (e.g., organic forms of Sn, Hg, and Pb) pose unique challenges to organisms due to their lipophilic nature or their incorporation into biological molecules (e.g., Se incorporation into methionine). The biotransformation rates of organometals are molecule specific, and use the same enzymes responsible for the metabolism of other organic xenobiotics (e.g., tributyl tin (TBT) is oxidized by cytochrome P450).

Excretion

There are several major and minor sites of metal elimination in fish including the hepatobiliary system, kidneys, gills, alimentary system, eggs, embryos, and skin and scales. Compared to mammals, fish have a limited capacity to excrete metals. Excretion is metal and species specific; for example, there is a threefold difference between the excretion rates of inorganic Hg (faster) versus methyl Hg (slower) that is partly responsible for the predominance of methyl Hg in fish tissues. Toxicokinetic modeling suggests that most metal elimination can be described by a two-compartment model where metal is first accumulated into a rapidly exchanging compartment from which metals are easily eliminated (e.g., complex to low-affinity intra- and extracellular ligands, i.e., Hg half-life ($t_{1/2}$ = days to weeks), and a slowly exchanging compartment in which metals are tightly bound (e.g., MTs, Hg $t_{1/2}$ = months to years).

Hepatobiliary excretion is a major route of metal excretion. The liver is highly perfused, has a high binding affinity for many metals (e.g., high-MT content), and has a biotransformation system for organometal metabolism and high titers of transporting ATPases (e.g., Cu-ATPase and a canalicular multiorganic anion transporter). Although believed to be an important route for metal excretion (e.g., Pb), specific details on renal metal excretory mechanisms are generally lacking for fish.

Bioaccumulation, Bioconcentration, and Biomagnification

Most metals are taken up by fish, that is, they bioaccumulate, and many have the potential to bioconcentrate (accumulation from the water to higher concentrations in the fish). Biomagnification is the accumulation from food resulting in higher concentrations in the fish. Most metals are not expected to biomagnify to any significant degree; however, lipophilic organic metals that are not easily biodegraded (e.g., triphenyltin and organoselenium) do so. For example, methyl Hg biomagnifies; it has high uptake and low elimination rates and attains its highest concentration at the top of the aquatic food chain in large predatory species such as the tuna, swordfish, and sharks.

Biological Effects and Toxicodynamics

The complexities of metal speciation and form on toxicokinetics are also reflected in diverse toxicodynamics (metal–receptor interactions, i.e., effects). Metals can be classified by their physiological mechanism of action into three broad categories, two that are based on action and one on location: monovalent metals (e.g., Ag(I) and Cu(I)) that affect Na transport; divalent metals (e.g., Cd and Zn) that disrupt Ca metabolism; and metals that act centrally (e.g., Pb and Hg).

Nonspecific protein binding is a hallmark of HM toxicity. Metals such as Hg and Cd bind nonspecifically to many proteins, particularly at sulfhydryl (–SH) groups, which are common functional groups on many proteins. This binding degrades the functionality of multiple proteins, which is why metal exposure can result in varied effects on many systems, and can result in multiple higher-level effects.

A discussion on metal toxicity would not be complete without mention of methods used to predict metal toxicity. Currently, there is much interest in the biotic ligand model (BLM) that is a chemical equilibrium-based model used as a tool to predict acute metal toxicity in aquatic organisms. Water-quality constituents can influence the extent of metal binding to the biotic ligand (e.g., Na or Ca channel proteins in gills) by competing with the metal for binding sites. The BLM is used to predict the degree of metal binding, accumulation, and toxicological response.

Specific metal toxicities in fish are highlighted below. They have been chosen by several criteria: relative toxicity, environmental relevance, and availability of toxicokinetic and toxicodynamic information.

Aluminum (Al)

The bioavailability and toxicity of Al varies with its chemical speciation. Bioconcentration is believed to be minimal and biomagnification insignificant. Acute (24–96 h) lethal concentration to 50% (LC_{50}) values in fish range from 0.095 to 235 mg l^{-1}.

In freshwater (FW) fish, Al exposure can cause significant ion disturbances and reduced plasma osmolarity. Failed ion regulation is arguably the primary cause for Al-related mortality (although several authors cite respiratory disturbance as the main mechanism). Some of these disturbances are due to change in gill Na^+/K^+-ATPase activity. In marine fish, low saltwater (SW) tolerance in Al-exposed fish is related to a decline in Na^+/K^+-ATPase activity.

At high Al concentrations, as with other metals, the other major physiological system affected is the respiratory system. Effects include hypertrophy and lifting of the outer epithelium, congestion of the secondary lamellae, and degeneration of chloride and epithelial cells. Reductions in apparent lamellar surface area and significant increases in gill mucus density further contribute to respiratory dysfunction, leading to increased coughing, hyperventilation, and decreased oxygen uptake.

Behavioral effects of Al include effects on predatory ability, swimming performance, and feeding activity, which may be caused in part by demyelination of nerves in the brain. Other neurotoxic effects on the olfactory organs of fish are also seen (**see also** **Toxicology**: The Effects of Toxicants on Olfaction in Fishes).

Cadmium (Cd)

The bioconcentration factors (BCFs) for Cd range from 152 to 756. The evidence as to whether or not Cd biomagnifies in aquatic foodwebs is inconclusive, but several studies indicate that biomagnification is insignificant.

The acute toxicity of Cd is highest at neutral pH, with LC_{50} values of 0.8–48 μg l^{-1} for FW fish. Marine species appear to be more tolerant, likely due to the effects of higher pH and other ions (e.g., Ca) on Cd bioavailability. For marine species, acute LC_{50} values range between 200 and 700 μg l^{-1}. Comparisons of toxicities between studies with most metals are difficult and can be improved by converting to common hardness values ($CaCO_3$ equivalents).

The main toxic effects of Cd in fish occur in gills and kidneys resulting in osmoregulatory disturbances. Specifically, its main effects occur through the obstruction of Ca uptake via Ca channels resulting in hypocalcaemia. This, however, appears to cause only moderate alterations in overall osmotic regulation: in FW, Cd causes modest declines in plasma Na and Cl; and in SW, the protective effects of other ions increase the concentrations necessary to elicit these effects.

Cd is an endocrine pathway modulator in teleosts. The hypothalamus–pituitary–gonadal (controlling sexual differentiation and reproduction) and the hypothalamus–pituitary–interrenal (controlling stress) axes are prime targets of Cd. Developmental effects, such as reduced growth and effects on reproduction, are effects likely mediated by this mechanism.

Cd also affects hematological parameters resulting in anemia. This occurs through several identified mechanisms: interference with hematopoiesis, potentially through a reduction in the absorption of Fe for hemoglobin, a slowing of erythrocyte maturation, and malformed and fragile circulating erythrocytes.

Cd exposure causes oxidative stress resulting in DNA fragmentation by stimulating the production of reactive oxygen species (ROS) and by inhibiting antioxidant enzymes that scavenge ROS; this may lead to apoptosis and pathological effects in several tissues. Cd is also immunomodulatory, inhibiting and stimulating different immune system components.

Chromium (Cr)

Cr does not significantly bioconcentrate or biomagnify in aquatic organisms. Cr exists as both trivalent (III) and hexavalent (VI) Cr, the latter being more toxic. Acute LC_{50} values of Cr(VI) in FW range from 0.1 to 930 mg l^{-1}. In SW, acute toxicity ranges from 16.3 to 200 mg l^{-1}. The acute toxicity of Cr(III) in FW ranges from 3.3 to 77.5 mg l^{-1}. Adverse effects in chronic studies include reduced growth, chromosomal aberrations, reduced disease resistance, and morphological changes. Cr is also a mutagen, carcinogen, and teratogen in vertebrates.

Copper (Cu)

There is a moderate potential for bioconcentration, but not biomagnification of Cu in fish. The acute LC_{50} value of Cu to FW fish can be as low as 2.8 μg l^{-1} in soft water and is inversely correlated with hardness. Toxicity in SW is much lower, with LC_{50} values in the range of 0.011–3 mg l^{-1}.

In FW, Cu exerts inhibitory effects on branchial ionoregulation during acute exposures. With metals that affect Na transport (e.g., via inhibition of Na^+/K^+-ATPase), the following sequelae are believed to occur; the inhibition of sodium uptake results in a redistribution of ions and water between internal compartments, which in turn triggers a sequence of events that potentially lead to cardiovascular collapse.

Chronic effects of Cu include effects on reproduction, growth, behavior, olfaction (**see also Toxicology**: The Effects of Toxicants on Olfaction in Fishes), development of embryos, and disease resistance.

Lead (Pb)

Pb can be bioconcentrated from water, but it does not biomagnify and concentrations tend to decrease with increasing trophic level. Although organic Pb compounds have the potential to biomagnify, evidence for such is contradictory.

As with other metals, the acute toxicity of Pb varies considerably with water hardness. In soft water, LC_{50} values range from 1 to 400 mg l^{-1}. In SW, LC_{50} values range from 0.3 to 3 mg l^{-1}. Organic Pb can be more acutely toxic; values as low as 3 μg l^{-1} are lethal to rainbow trout (*Oncorhynchus mykiss*).

Pb exerts toxic effects in fish through disruption of Ca balance and the interference with Na and Cl regulation, which places its toxic mechanism midway between metals such as Cd and Cu. Lead-induced ionoregulatory toxicity is not only exclusively a branchial phenomenon, but also involves the disruption of ionoregulatory mechanisms at the kidney and digestive tract.

Pb causes cancer, adversely affects liver and thyroid function, and decreases disease resistance. Other effects include muscular, spinal, and neurological degeneration, growth inhibition, reproductive problems, and hematologic effects such as disruption in hemoglobin synthesis.

Mercury (Hg)

There is a high potential for Hg bioconcentration and biomagnification (in organic form), with BCFs up to 100 000. Organic Hg compounds are more readily absorbed and poorly excreted in comparison with inorganic forms.

Acute LC_{50} values for inorganic Hg range from 150 to 900 μg l^{-1} in both FW and SW. Acute toxicity concentrations for methyl Hg range from 24 to 125 μg l^{-1}. Unlike most other toxic metals, water hardness has a negligible effect on Hg toxicity.

Hg causes altered osmoregulation in both FW and SW fish, although unlike other metals, the effects are not diminished in SW. Methyl Hg appears to produce osmoregulatory disturbances at concentrations approximately 10–20 times lower than inorganic mercury in FW fish.

The primary targets of Hg are the central nervous system (CNS) and kidneys in fish. At concentrations below 1 μg l^{-1}, Hg can cause neurological effects including loss of appetite, brain lesions, cataracts, abnormal motor coordination, and behavioral changes. Significant anemia and reduced oxygen uptake occur in fish exposed to inorganic Hg, possibly through accumulation in the kidney and inhibition of uroporphyrinogen I synthetase (a heme biosynthetic enzyme) as well as through reductions in the deformability of erythrocytes and premature destruction. Other sublethal adverse effects that are commonly reported include impaired growth, reproduction, and development. Reproductive effects are partly mediated by suppressed levels of plasma sex steroids, inhibition of gonadal development, altered reproductive behavior, reduced egg production, and reduced spawning.

Nickel (Ni)

Little bioconcentration of Ni occurs, with BCFs in the range of 2–52. There is also little evidence of significant biomagnification of Ni. Ionic Ni is very toxic to fish embryos (LC_{50} 11–113 μg l^{-1}), but considerably less toxic in larger fish (7–140 mg l^{-1} depending on water hardness).

Unlike many metals which cause respiratory distress only at higher concentrations, the main effect of Ni is on respiration (arguably as with Al) rather than on ionoregulation (e.g., Cu, Ag, Cd, and Zn), most likely causing sufficient gill damage to critically impair branchial gas exchange, leading to eventual suffocation. Other effects include altered immunological parameters, reduced growth, and there is some evidence that it is a carcinogen and weak mutagen as well.

Selenium (Se)

Se can significantly bioconcentrate and biomagnify. The bioaccumulation of Se through the diet is believed to be greater than the direct uptake from water. Organoselenium forms (e.g., selenoamino acids (selenomethionine, selenocysteine, and selenocysteine)) are much more bioavailable than inorganic forms and play the most important roles in Se ecotoxic effects. These forms can be transferred through various aquatic consumers into the top-level piscivorous fish.

Se functions as both an essential nutrient and environmental toxicant, with a narrow margin between essential and toxic effects. Acute LC_{50} values for Se range from 0.62 to 96.8 mg l^{-1} for FW fish, and range from 0.6 to 86 mg l^{-1} in marine species. Data suggest that selenite-Se is more toxic than selenate-Se.

Adverse effects observed in fish exposed to Se include loss of equilibrium and other neurological disorders, liver damage, reproductive failure, reduced growth, reduced locomotion, chromosomal aberrations, reduced hemoglobin and increased white blood cell count, and necrosis of the ovaries. Research to date indicates that the most ecologically significant Se toxicity in fish arises from maternally transferred Se that accumulates in egg yolks during vitellogenesis, likely as selenoamino acids. Deformities and edema occur when developing larvae utilize the yolk sac resulting in larvae with gross abnormalities.

Silver (Ag)

Ag is one of the most toxic metals to fish. The LC_{50} value for Ag (as nitrate) in FW is usually in the range of 5–70 $\mu g\ l^{-1}$. Ag chloride is 300 times less toxic, Ag sulfide is 15 000 times less toxic, and Ag thiosulfate is 17 500 times less toxic. Water hardness is an important factor affecting the toxicity of most metals, but appears to be less important for Ag. The toxicity of Ag is considerably lower in SW (acute LC_{50} range: 330–2700 $\mu g\ l^{-1}$).

The primary mechanism of toxicity in FW is the inhibition of active Na and Cl uptake at the gills, whereas the intestine has been indicated as the site of toxicity in SW fish. As described for Cu, this effect can lead to critically low blood volume, high viscosity of the blood, and high blood pressure leading to mortality. Ag affects gill structure and function at high concentrations leading to asphyxiation, convulsions, and abnormal surfacing behaviors. At environmentally realistic concentrations, toxicity is not via suffocation, but via osmoregulatory impedence. Chronically elevated concentrations of Ag can also cause developmental abnormalities and reduced growth.

Thallium (Tl)

Fish exposed simultaneously to Tl sulfate (Tl_2SO_4) and Tl had BCF values of 34, and Tl is not expected to biomagnify. Tl can be as toxic as Cu on a weight basis with acute LC_{50} values ranging from 0.86 to 132 $mg\ l^{-1}$ in FW fish. Tl can also cause reductions in larval fish growth and reduced embryo hatchability.

Tin (Sn)

The most environmentally important Sn compounds are organotins. The bioconcentration potential of organotins is directly related to the lipophilicity of the specific organotin. For example, BCFs for TBT have been found to range from 200 to 4580 compared to lower values for water-soluble inorganic Sn.

Acute toxicity of organotin compounds is strongly influenced by the length of the alkyl chains attached to the tin. TBT is generally less toxic than trimethyl tins (TMTs)- and triethyl tins (TETs). LC_{50} values for TBT range from 2.6 to 12.7 $\mu g\ l^{-1}$. Of the tri-substituted organotins that exert the highest toxicity, TMT and TET are primarily neurotoxic, while TBT has a broader range of toxic effects. A multitude of cellular effects has been seen in fish exposed to organotins and includes disturbance of Ca^{2+} homeostasis and the induction of apoptosis, DNA fragmentation, inhibition of oxidative phosphorylation and ATP-synthesis, and inhibition of ion pumps. Although TBT exposure leads to endocrine disruption, and developmental and reproductive abnormalities, its proximal mechanism(s) of action involves acting as a Ca ionophore causing general membrane perturbation leading to apoptosis.

TBT exposure can also adversely affect egg hatchability, larval viability, and survival and growth in fish. These effects are often associated with overall retardation of development including striking morphological effects and severe malformations of the body axis of larvae including CNS and spinal cord malformalities.

Behavioral effects of organotins include alterations to swimming behavior that were believed to be associated with neurotoxicological manifestations in the brain. Interestingly, TBT accumulates in brain regions via axonal transport from water-exposed sensory organs.

The immunotoxicity of organotin compounds is only partially understood in fish; however, it is believed that TBT oxide and dibutyl tin (metabolites of TBT) induce thymic atrophy, and hyperplasia of the hematopoietic interstitial tissue of kidneys resulting in reduced immune defense parameters.

Zinc (Zn)

Zn can bioconcentrate, with typical BCFs around 150. Biomagnification is not a significant process in zinc toxicity, and concentrations can decrease with increasing trophic level. In FW, acute LC_{50} values range between 63 and 170 $mg\ l^{-1}$. Zn interferes with Ca uptake at the gill that, like Cd, causes hypocalcaemia or calcium deficiency. To a lesser extent, Zn disturbs Na and Cl fluxes, resulting in a net branchial ion loss in FW. Irreversible destruction of the gill epithelium occurs at high Zn concentrations causing reductions in oxygen uptake, tissue hypoxia, osmoregulatory failure, and acidosis. Long-term Zn toxicity affects growth, egg fragility and mortality, and reproduction.

Glossary

Bioaccumulation The process by which substances accumulate in the tissues of living organisms from all sources in the environment.

Bioconcentration The accumulation of chemicals or metals in living organisms to higher concentrations than in environment from water.

Biomagnification Increase in concentration of chemicals or metals through the food chain to highest levels in highest trophic level.

Contaminant Any substance that enters a system where it is not normally found.

Dose Amount of chemical absorbed, usually in mass per unit weight.

Dose–response The relationship between the amount of chemical absorbed and the effects observed.

Endocrine disruptors An exogenous substance (xenobiotic) that interferes with endocrine function, the synthesis, transport, degradation, or actions of hormones.

Hydrophilicity (water linking in Greek) A physical property of a molecule that can transiently bond with water (H_2O) (dissolve in it) through hydrogen bonding.

Hydrophobicity (water linking in Greek) The physical property of a molecule that is repelled from a mass of water.

Lipophilicity (fat liking in Greek) The ability of a chemical compound to dissolve in fats, oils, lipids, and nonpolar solvents.

Octanol–water partition coefficient The octanol–water partition coefficient or K_{ow} is the ratio of the concentrations of a chemical in an octanol and water system.

Organic compound A compound that contains one or more C–H bonds.

Organochlorine An organochlorine is an organic compound containing at least one covalently bonded chlorine atom.

Personal-care products Consumer products used for beautification and in personal hygiene.

Pharmaceutical A pharmaceutical drug can be loosely defined as any chemical substance intended for use in the medical diagnosis, cure, treatment, or prevention of disease.

Pollutant Contaminant that adversely alters properties of the environment.

Polybrominated diphenyl ethers (PBDEs) Organobromine compounds that are used as flame retardants, and are polyhalogenated compounds, consisting of two halogenated aromatic rings.

Polychlorinated biphenyls (PCBs) A class of organic compounds with 1–10 chlorine atoms attached to biphenyl, a molecule composed of two benzene rings.

Polycyclic aromatic hydrocarbon Polycyclic aromatic hydrocarbons (PAHs) are also known as polyaromatic hydrocarbons or polynuclear aromatic hydrocarbons, and are chemical compounds that consist of two or more fused aromatic rings.

Toxicodynamics The process of interaction of chemical substances with target sites leading to adverse effects.

Toxicokinetics Processes of the uptake of potentially toxic substances, biotransformation, distribution, and elimination.

Xenobiotic Chemicals that are foreign to a biological system.

Introduction

In the sixteenth century, Paracelcus, a German-Swiss alchemist and physician, highlighted one of the most fundamental aspects of toxicology in his quote: “All things are poison and nothing is without poison, only the dose permits something not to be poisonous.” Today, concern about environmental contamination and pollution is usually limited to those compounds that have relatively high toxicity. Nature produces such chemicals; for example, the potent bacterially derived neurotoxin tetrodotoxin is used as a defensive biotoxin and predatory venom by a number of fish species including puffer and angelfishes. However, it has been the relatively recent phenomena of industrial pollution and the release of novel synthetic compounds into the biosphere that has heightened interest and concern, and focused research toward understanding the fate and effects of harmful substances to humans and wildlife, including fish.

The Stockholm Convention (2001) was an international convention that brought into force an agreement that essentially moves to outlaw chemical substances that persist in the environment, bioaccumulate through the food web, and pose a risk of causing adverse effects to human health and the environment. This applies particularly to persistent pollutants including the so-called dirty dozen chemicals (aldrin, chlordane, dieldrin, endrin, heptachlor, hexachlorobenzene, polychlorinated biphenyls (PCBs), dichlorodiphenyltrichloroethane (DDT), polychlorinated dibenzo-*p*-dioxins (PCDDs; dioxins), polychlorinated dibenzofurans (PCDFs; furans), mirex, and toxaphene).

Several definitions exist for organic compounds (with many exceptions) and include compounds containing one or more C–H bonds, compounds that include C–C bonds, or molecules that simply contain carbon. Many of the molecules classified as organic today have no connection whatsoever, material or structural, to any substance found in living organisms (the historical definition of the word). In toxicology, organic compounds are classified as natural or synthetic. Natural organics refer to toxins that are produced by plants or animals. Compounds that are prepared by reaction of compounds (natural or not) are referred to as synthetic. This article focuses on anthropogenic synthetic chemicals (foreign chemicals are often called xenobiotics) of environmental significance.

Understanding the toxicity of environmental contaminants to fish requires knowledge regarding their environmental fate (to understand contact between fish and chemical, i.e., exposure), toxicokinetics (absorption, distribution, biotransformation, and excretion of the chemical), and toxicodynamics (effects of the toxicant) according to the toxic action paradigm (**Figure 1**).

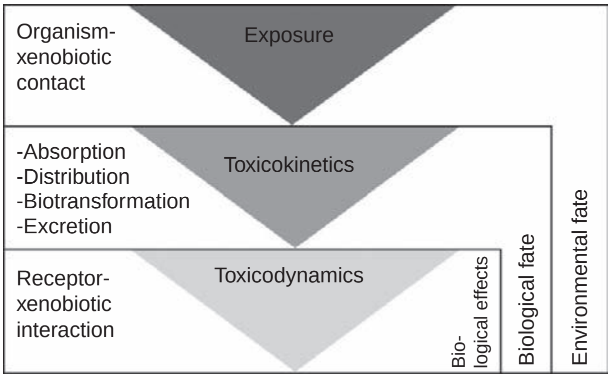

Figure 1 The toxic action paradigm. Knowledge regarding environmental fate, toxicokinetics, and toxicodynamics is fundamental to understanding how organic chemicals impact fish and other organisms.

Biological Fate

The distribution of a chemical in the aquatic environment is determined by a complex interplay between the physico-chemical properties of the compound and a diverse environment. For the purpose of understanding the partitioning of such chemicals, the aquatic environment can be visualized as several units: the atmosphere, water, sediments, and biota. Two key chemical characteristics, vapor pressure and water solubility, determine the partitioning and final concentrations of organic chemicals in the environmental units.

Vapor pressure is a measure of the tendency of molecules and atoms to escape from a liquid or a solid into the gas phase. The higher the vapor pressure of a compound, the higher is its partitioning into the atmosphere. Toxic chemicals such as persistent organic pollutants (POPs; even with low vapor pressures) can volatilize and be transported globally, affecting ecosystems far from the original pollution sources. Equally interesting, volatilization from contaminated water bodies can aid in their decontamination. For example, the Great Lakes decreased their combined levels of PCBs by 10 tons from 1992 to 1996 by chemical movement into the atmosphere.

Water solubilities of organic chemicals can range from very water soluble (hydrophilic, e.g., ionized or polar molecules) to those such as dioxins and polybrominated diphenyl ethers (PBDEs), which are hydrophobic (water fearing) and have very limited water solubility. Hydrophilic molecules will dissolve in the water easily, whereas hydrophobic chemicals tend to bind to sediment or the lipid of organisms. K_{ow} is a value that describes the partitioning of a chemical between octanol (an organic solvent and a surrogate for lipids in biota and for organic carbon) and water. K_{ow} is arguably the most important measure of a compound's hydrophobicity, associated environmental partitioning, and uptake potential in organisms. Chemicals with log K_{ow} values between 4 and 8 are hydrophobic, while lower values are indicative of more water-soluble compounds.

Bioaccumulation of organic chemicals is usually defined as the uptake of chemical from any matrix in the environment by an organism. Bioconcentration specifies the accumulation of chemical from the abiotic environment (e.g., from water to gills or through skin) into an organism, resulting in concentrations higher than in the environment. Biomagnification specifies the accumulation of chemical from its diet to higher concentrations than are found in its prey. Biomagnification, therefore, accounts for increases in the concentrations of some chemicals through successive trophic levels due to food alone. A high log K_{ow} value and a low biodegradation rate are the two factors primarily responsible for bioconcentration and biomagnification. For example, in Lake Michigan, 1,1-dichloro-2,2-bis(p-chlorophenyl)ethylene (DDE: a high log K_{ow} organochlorine (OC) pesticide) was a strongly biomagnified compound, increasing 28.7 times in average concentration from plankton to fish. PCBs increased 12.9 times in average concentration from plankton to fish, while toxaphene increased by an average factor of 4.7. A simple way of viewing this tendency is that the greater the K_{ow} of a compound, the less it likes being dissolved in the water surrounding the fish and the more it likes being dissolved in the lipids of the fish.

Chemical Uptake

The three major sites of uptake for organic chemicals in fish are the integument, gills, and digestive system. Integuments can act, in part, as barriers to the outside environment and limit the absorption of xenobiotics (even with the secondary skin circulation in fish), partially due to the presence of scales in fish. Conversely, respiratory systems and digestive systems are designed for transfer between the organism and the environment. For example, extraction efficiencies of organic chemicals from the aqueous environment can be typically >80% at the gills (e.g., pentachlorphenol). Log K_{ow} correlates fairly well with the extent of uptake in fish, with compounds having higher log K_{ow} values tending to accumulate more rapidly. For chemical concentration ratios that might be expected in nature, gill uptake can account for the majority of a fish's body burden for chemicals of log K_{ow} values of <5, but as the K_{ow} increases, the contribution from dietary uptake rapidly rises largely because there is less of the chemical dissolved in the water and more in the food. Thus, K_{ow} is primarily responsible for altering the bioavailability of the chemical to either the gill or gut; the ease with which a chemical can cross the gill or gut membrane also increases with K_{ow}.

Several mechanisms exist by which organic chemicals can move into cells. Simple passive diffusion is the primary mechanism by which lipophilic/hydrophobic toxicants move into cells. The lipid bilayer of the cell membrane is a barrier to most nonionized hydrophilic molecules and ions, although small molecules of approximately molecular weight (MW) <100 can traverse this barrier by diffusing through aqueous channels. In addition to this, larger water-soluble molecules can still gain entry into cells through active transport and facilitated diffusion. In these cases, membrane-associated carrier proteins provide transport and are linked either to energy-producing enzymes or to the co-transport of other molecules.

Chemical Biotransformation

Biotransformation is the enzymatically catalyzed transformation of a parent (original) xenobiotic into metabolic products called 'metabolites'. The excretory mechanisms of fish are essentially water based; excretion of foreign chemicals is into water via the gills, urine via the kidneys, or feces via the hepatobiliary route. Any absorbed hydrophobic/lipophilic contaminant, such as PCBs, PBDEs, or OC pesticides, cannot utilize these excretory pathways unless the parent chemical is transformed into more water-soluble products by biotransformation. Thus, once high K_{ow} chemicals are absorbed, it is very difficult to excrete them back to the aquatic environment.

Biotransformation results in water-soluble metabolites that are more easily excreted. Biotransformation reactions in fish are categorized into phase I (asynthetic) and phase II (conjugation or synthetic) reactions (**Figure 2**). In phase I reactions, a chemical can undergo oxidation, reduction, or hydrolysis reactions (the three most common in fish), which either reveals or adds on a polar functional group (e.g., –OH and –COOH), usually rendering the molecule more water soluble than the original. The cytochrome P450-dependent monooxygenases comprise a group of heme-containing enzymes involved in the metabolism of

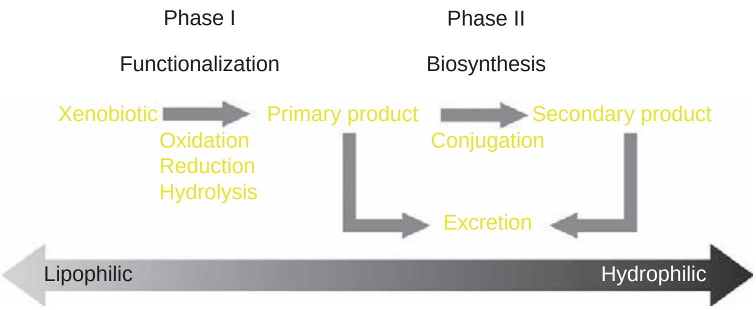

Figure 2 Biotransformation processes in fish. Phase I reactions add or unmask polar functional groups to a xenobiotic, while phase II reactions conjugate xenobiotics or their phase I metabolites to endogenous molecules. Generally, both types of reactions result in more water-soluble metabolites.

thousands of endogenous and xenobiotic compounds. The various P450 forms have been classified into families and subfamilies based on their amino acid sequences and are well studied in fish.

Phase I reactions prepare xenobiotics for phase II reactions if they are not rendered water soluble enough to be excreted. In phase II reactions, an endogenous molecule (e.g., glutathione, glucuronic acid, sulfate, and amino acids (e.g., taurine)) is covalently bound to a polar functional group on either the original chemical (e.g., pentachlorophenol has an –OH group), or one of its metabolites (e.g., the phase I metabolite of the polycyclic aromatic hydrocarbon (PAH) benzo[a]pyrene, 3-OH B[a]P) producing a phase II metabolite which is very water soluble and easily excreted. Phase II metabolites are usually less toxic than the parent molecule. Even so, the biotransformation of many chemicals via phase I reactions can result in more toxic metabolites, a process called 'bioactivation'. For example, the PAH B[a]P is metabolized to B[a]P 7,8-dihydrodiol-9,10-epoxide which is the ultimate carcinogenic form of this PAH and responsible for increased neoplasia found in flatfish associated with PAH-contaminated sediments (**Figure 3**). The bioconcentration and biomagnification of high K_{ow} contaminants in fish (e.g., methylmercury, OC pesticides, and PCBs) are due in part to their recalcitrance to biodegradation by this process.

Biotransformation capability can be enhanced by prior exposure to some contaminants in a process called 'induction'. For example, P450 isoforms in the 1A (CYP1A) subfamily are inducible by planar PAH and halogenated aromatic hydrocarbon (HAH), including chlorinated biphenyls, dibenzo-*p*-dioxins, and dibenzofurans. Induction of cytochrome CYP1A is controlled by the Ah receptor (AhR), a soluble protein with a high binding affinity for planar PAH and HAH. The aryl hydrocarbon receptor nuclear translocator (ARNT) and the AhR together form a transcription factor complex through which altered gene expression and toxicity occur. Their dimerization is dependent upon high-affinity binding of planar PAH and HAH to the AhR. The AhR:ARNT complex then binds specific, *cis*-acting DNA elements, altering the transcription of target genes, including phase I and phase II detoxifying enzymes, growth factors and their receptors, and numerous unidentified genes. In addition to the AhR, other factors such as temperature, hormonal status, stress, and the presence of inhibitors may influence the expression and function of fish biotransformation enzymes.

Chemical Excretion

The main excretory routes in fish for organic xenobiotics mentioned above include the branchial, urinary, and fecal routes. High K_{ow} compounds are not easily excreted via any of these routes because they are water based. However, some ionizable organics (e.g., chlorinated

phenols) may be excreted via the gills and kidney. As undissociated molecules, they may pass through epithelial membranes, becoming ionized (and hence water soluble) in the external microenvironment of the gill or in urine, depending on pH of the aqueous medium. Few organic chemicals or their metabolites are excreted via the gills other than by this mechanism.

Most elimination of organic compounds or their biotransformed derivatives occurs via the kidneys and hepatobiliary route. In teleost kidney tubules and in hepatocytes, as well as other tissues, a number of xenobiotic (or metabolite) export pumps exist, which result in efficient vectorial transport of their substrates from the basolateral (facing extracellular fluid) to the luminal side of cells (facing canaliculi or lumen for excretion into bile or urine). These pumps include members of the adenosine triphosphate (ATP)-binding cassette (ABC) superfamily of proteins (**Figure 4**). The ABC family of membrane proteins accepts substrates with an unusually wide range of structural features. *p*-Glycoprotein accepts primarily cationic compounds. Multidrug resistance proteins (Mrps) accept anionic compounds, and both accept uncharged molecules and some polypeptides. The expression of xenobiotic efflux pumps in kidney and liver can be upregulated several fold over a period of days to weeks in response to a number of signals, including, substrates, toxicants, and heat stress. At the basolateral membrane are members of the solute carrier transport superfamily of proteins, the organic anion transporters (Oat1 and -3) and organic cation transporters (Oct2), as well as efflux pumps from the Mrp subfamily (Mrp1). Oat1 exhibits a broad substrate specificity and is responsible for the cellular uptake of most amphiphilic organic anions. High levels of expression of Mrp2, multidrug resistance (MDR) or *p*-glycoprotein, and organic cation/carnitine transporter (OCTN1) are seen in barrier and excretory tissues, for example, intestine, blood–brain barrier, liver and renal proximal tubule, and are targeted to the luminal membrane, which puts them in the right location to limit xenobiotic entry into the body and brain and to drive excretion into bile and urine.

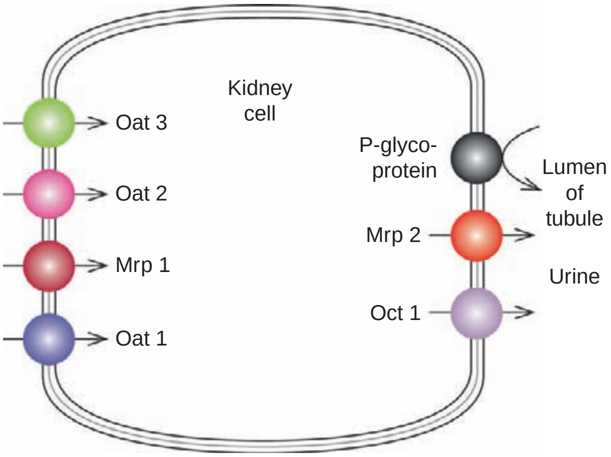

Figure 4 Various transport proteins are involved in excretory tissues or tissues in contact with the environment. Here, several known transporters in fish are shown on the basolateral side of the cell facing the extracellular fluid or blood (organic anion transporters (Oat) and multidrug resistance protein (Mrp)) and on the luminal side of the cell facing the environment (in this case, the lumen of the kidney tubule containing urine; organic cation transporter (Oct), Mrp, and P-glycoprotein).

Multixenobiotic resistance (MXR) is a phenomenon that increases the potential for survival of fish in polluted environments through enhanced expression of one or more MDR-like transport mechanisms that restrict xenobiotic uptake. Protein analysis has indicated the presence of proteins immunologically related to *p*-glycoprotein in tissues from marine and freshwater fish. Such transport systems are present at some basal level in animals maintained in unpolluted environments and they appear to be upregulated on exposure to pollutants.

Specific Organic Contaminants

Pesticides

Pesticides can be broadly classified as insecticides, herbicides, and fungicides. Insecticides fall into three major groups: the OCs, organophosphates (OPs), and carbamates (**Figure 5**). Legacy OCs include DDT, chlordane, dieldrin, aldrin, endrin, heptachlor, lindane, methoxychlor, and toxaphene (**Figure 5**). OC insecticide action is through disruption of the sodium channels of neurons, resulting in continuous firing of nerves and paralysis. Their lethal concentrations (LCs) vary greatly, and they have been phased out because of their high toxicities (teleost LC_{50} values in low $\mu g\ l^{-1}$), persistence, and potential to bioaccumulate. OC pesticides, such as DDT, are extremely persistent and biomagnify; DDT and its metabolite DDE can act as endocrine disruptors, interfering with hormonal function of estrogen, testosterone, and other steroid hormones, in fish and vertebrate predators.

OPs and carbamates have largely replaced OC pesticides due to their lowered persistence. Their mechanism of action is to inhibit acetylcholinesterase, allowing the neurotransmitter acetylcholine in cholinergic nerves to continue stimulating postsynaptic nerves indefinitely, causing muscle weakness or paralysis. OPs are less toxic to fish (LC_{50} values in fish in the mg l^{-1} range) than OCs, but have in some cases been replaced by less toxic carbamates.

All of the above insecticides, including others in the botanical (e.g., pyrethroids) class, as well as herbicides and fungicides, have molecule-specific effects. The effects can have a variety of target sites and toxicities; for example, hematological, gas exchange, olfactory (**see also Hearing and Lateral Line**: Lateral Line Structure), ionoregulatory and osmoregulatory, carbohydrate metabolism, the immune system, as well as neurological effects

A representative PAH, benzo[a]pyrene is also shown.

including impaired learning behaviors, slowed reflexes, and reductions in reproductive success in fish.

Regulatory attention has resulted in bans against many legacy pesticides and restricted the use of many OPs and carbamates, and has led to the development of new pesticides with less persistence and more target specificity. This group of newer compounds is called current-use pesticides (CUPs). Concerns with CUPs include high usage, the prevalence of these chemicals in the environment at low levels, unknown effects on nontargets, and concerns of synergism between compounds. To date, several significant sublethal effects have been demonstrated with CUPs in fish, including moderate immunomodulation, endocrine disruption, energetic costs, and effects on olfaction.

Polycyclic Aromatic Hydrocarbons

One of the most ubiquitous and important classes of environmental contaminants are the PAHs, which consist of two or more fused benzene rings which may have alkyl side groups containing nitrogen, sulfur, and oxygen (**Figure 5**). These contaminants are produced mainly as a result of incomplete combustion of fossil fuels or biomass, as well as being constituents of petroleum. PAH environmental distribution and toxicity are structurally dependent and although there is a wide range of water solubilities of PAHs, they are generally considered to be a hydrophobic class. The degree to which fish accumulate various PAHs from water, sediment, and food depends upon the physical and chemical properties of the PAH (e.g., size and log K_{ow}), environmental conditions (e.g., dissolved oxygen content (DOC), and biological factors (PAH metabolism and depuration rates, feeding characteristics of organisms, fat content of tissue, life stage, etc.)) PAHs generally do not bioconcentrate or biomagnify in fish due to extensive metabolism.

In general and with some exceptions, fish appear to be the most sensitive of aquatic organisms to PAHs. The acute toxicity of PAHs varies greatly with the molecule, but generally short-term effects are due to low MW PAHs (LPAHs), with toxicity increasing with increasing substitution on the molecule. The minimum LC_{50} for LPAHs is $30\,\mu g\ l^{-1}$ for phenanthrene in rainbow trout (*Oncorhynchus mykiss*). LPAHs are relatively more soluble in water than high MW PAH (HPAH) and, therefore, LC_{50} values for HPAHs may not reflect reality because of their low solubility. Alkyl homologs of PAHs are generally more toxic to fish than the parent compound. Several PAHs, accumulated by aquatic organisms during exposure, have been shown to be severely toxic when the contaminated organisms were exposed to sunlight or ultraviolet radiation. The phototoxicity of a PAH is a function of the efficiency of conversion of ground-state molecules to the excited triplet state and the probability of the excited intermediate reacting with a target molecule.

PAHs have common and chemical-specific chronic mechanisms of action (e.g., activation of the AhR pathways) underlying their toxicity. The toxicological significance of environmental contamination of PAHs depends in large part on the metabolic fate of the compounds inasmuch as metabolism can lead either to the formation of toxic and carcinogenic intermediates or to detoxification. A wide variety of chronic effects have been reported for PAH exposure in fish. LPAHs are known irritants, and can stimulate the ascending neural pathways of the hypothalamus–pituitary–interrenal (HPI) axis and cause a stress response. In addition, these LPAHs can cause gill hyperplasia and other morphological effects. PAHs can also affect the functioning of gills by causing ionoregulatory disturbances. Effects of PAHs in larval and juvenile fish include morphological (e.g., necrosis of brain and spine), histopathological, and genetic damage, as well as affecting development (e.g., arrested development and reduced hatching success). PAHs in the $\mu g\ l^{-1}$ range can affect immune system components and pathogen resistance. PAHs have been shown to reduce the swimming ability of fish and potentially reduce marine survival in salmonids. Some PAHs may act directly as endocrine disruptors, targeting multiple sites in the HPI axis including the perception of stimuli, the pituitary or adrenocortical tissues, the synthesis and secretion stress hormones (e.g., cortisol), and target tissue responsiveness to glucocorticoid stimulation.

Some HPAHs are mutagenic, carcinogenic, and inducers of tumors in fish. During biotransformation, some PAHs are converted to arene oxide intermediates, which can be carcinogenic and/or mutagenic. Fish collected from PAH-contaminated marine areas show a high incidence of hepatic lesions including neoplasm.

Dioxins

Dioxins are organic chemicals that contain 210 structurally related individual PCDDs and PCDFs. They are produced in the incineration of chlorine-containing substances, chemical and pesticide manufacturing, and in the bleaching of paper (**Figure 5**). These chemically related compounds vary in their physical and chemical properties and toxicity; however, generally, higher chlorination leads to lower degradation rates, higher partitioning to sediments and biota, and increased toxicity (the most toxic is 2,3,7,8-tetrachloro-dibenzo-*p*-dioxin (2,3,7,8-TCDD)). Dioxins are highly persistent in the environment with reported half-lives in sediment ranging from months to years. Bioaccumulation factors vary among the congeners and generally increase with chlorine content up through the tetra congeners and then generally decrease with higher chlorine content. For example, bioconcentration factors (BCFs) for TCDD in fish ranges from 37 900 to 128 000, whereas BCFs for the octo-chlorinated dibenzo-*p*-dioxin (OCDD) congeners range from 34 to 2226.

Fish, as oviparous vertebrates, are particularly sensitive to the developmental effects of dioxin. This fact has led to reduced and, in some cases, failed recruitment of young fish into breeding populations.

The mechanism of action for dioxin and dioxin-like compounds is mainly through activation of AhR and subsequent transcriptional upregulation of the AhR gene battery that includes CYP1A. However, the role of these genes in dioxin-induced toxicity is still not well understood. Blue sac disease is a syndrome in fish embryos and larvae that includes induction of CYP1A enzymes, yolk sac and pericardium edema, hemorrhaging in the head and tail regions, craniofacial deformities, a wasting syndrome, and early larval mortality, which are seen in TCDD and other chlorinated, planar aromatic compound exposures. This toxicity may begin by AhR-mediated CYP1A induction and its increased activity, resulting in an increase in reactive oxygen species (ROS) through an inefficient coupling of the P450 complex with nicotinamide adenine dinucleotide phosphate (NADPH)-P450 oxidoreductase or cytochrome b_5. Enhanced localized oxidative stress in the cardiovascular system, and in particular the vascular endothelium of the developing embryo, leads to an increase in membrane permeability, ischemia, and circulatory failure. This mechanism has been identified as a primary target of dioxin-induced toxicity. Events such as apoptosis in the digestive tract, gills, and neural tissues and cells lead to a myriad of secondary effects in various tissues affected by dioxins which, in turn, may lead toward eventual toxicity and death.

Polychlorinated Biphenyls

PCBs (commonly called Aroclors) are organic compounds with 1–10 chlorine atoms attached to biphenyl (209 distinct congeners, **Figure 5**). They were widely used as dielectric fluids in transformers, capacitors, and coolants. PCBs are still prevalent environmental contaminants worldwide, even though they were banned in most countries in the 1970s and prescribed by the Stockholm Convention in 2001.

PCB persistence, biomagnification potential, and toxicity are all congener specific. PCBs bioconcentrate and biomagnify to a high degree (maximum BCF was 975 000 when expressed on whole fish basis). Aroclors containing 42–54% chlorine appear to be the most acutely toxic formulations of PCBs with values ranging from 100 to 3000 $\mu g\ l^{-1}$. Data suggest that PCBs are as toxic to marine organisms as they are to freshwater organisms.

Coplanar PCBs can mimic the effects of dioxin as agonists of the AHR (those halogenated in meta- or para-positions are among the most toxic PCBs), and the similarity of certain congeners to biological ligands of steroid nuclear receptors can result in endocrine system disruption. Select PCB congeners can produce (although less than dioxins) fish early-life-stage mortality associated with yolk sac edema and hemorrhaging (blue sac disease). Because only a small portion of the total mass of PCB mixtures contains coplanar congeners that elicit AhR-mediated dioxin-like effects, it is possible that non-dioxin-like effects may also play a role in PCB toxicity through various mechanisms. While environmental levels of PCBs do not produce overt lethality in adult fish, however, their presence in combination with other chlorinated dioxins and furans poses an increased risk to early-life-stage survival of many fish species. Reproductive abnormalities induced by PCB exposure include altered sex ratios, testicular abnormalities such as disorganization of spermatogenic elements and inhibition of spermatogenesis, altered steroid biosynthetic patterns, reduced fertilization, reduced egg production and limited development of eggs, and complete reproductive failure. Other effects in fish include formation of neoplasms, as well as biochemical and cellular perturbations such as anemia, hyperglycemia, and altered cholesterol metabolism.

Chemicals of Emerging Concern

Polybrominated Diphenyl Ethers

PBDEs consist of two halogenated aromatic rings, and are classified according to the average number of bromine atoms in the molecule (**Figure 5**; 209 possible congeners). They are used as flame retardants in a wide array of products including plastics, textiles, polyurethane foam, and other materials. PBDEs have emerged as a major environmental pollutant. They are similar in structure to PCBs and resist degradation in the environment, and have been detected in fish that feed in offshore waters. This indicates that they have become incorporated into pelagic and deep-sea food webs. The toxicology of PBDEs is not well understood, but PBDEs have been associated with tumors, neurodevelopmental toxicity, and thyroid hormone imbalance. The toxicology of PBDEs to fish is not well understood. However, PBDEs are believed to bind to the same cellular receptors and to have toxic effects that are similar to those reported for the structurally related PCBs. PBDEs possess endocrine-disrupting properties; hydroxy-PBDE congeners have structural similarities with the thyroid hormones and short-term exposure to less-brominated PBDE congeners may interfere with thyroid function and disrupt hormonal balance. Embryonic exposure can result in the development of morphological, cardiac, and neural deficits that impair survivorship for fish larvae. Behavioral effects include irritation, twitching, abnormal swimming behavior, and labored respiration. Some species show reduced survival of young at hatch and reduced growth and condition, as well as reproductive effects including lower sperm production. However, the concentrations of PBDE required to cause most of the above effects in fish were considerably higher than recorded tissue or environmental concentrations. Therefore, the risk of PBDE contamination to fish while currently unknown may be low.

Pharmaceuticals and Personal Care Products

Pharmaceuticals and personal care products (PPCPs) are bioactive chemicals that include prescription and over-the-counter therapeutic drugs, veterinary drugs, fragrances, cosmetics, sun-screen products, and diagnostic agents and nutraceuticals (e.g., vitamins) from a variety of sources including human activity, residues from pharmaceutical manufacturing, residues from hospitals, illicit drugs, veterinary drug use especially antibiotics and steroids, and agribusiness. PPCPs can enter aquatic environments through human and animal excretion as well as disposal of unwanted medications, some of which are not amenable to wastewater treatment processes. Natural and synthetic estrogens from the contraceptive pill are an example of a PPCP that has effects on fish populations at concentrations found in the environment, including increased feminization of males, intersex, hermaphroditic fish, female-skewed sex ratios, increased vitellogenin synthesis, arrested reproductive development in males, reduced fecundity, and induction of developmental abnormalities.

Perfluorooctane Sulfonate

Perfluorooctane sulfonate (PFOS; **Figure 5**) has been manufactured for over 50 years and has been used for several industrial and commercial purposes including fire retardants and stain-resistant treatments. Fluorinated organic compounds such as PFOS have not received due toxicological attention because their measurement is difficult. Recently, it has been reported that PFOS is widely distributed on a global scale and can be persistent and bioaccumulative and can be found worldwide in wildlife. Related perfluorinated compounds have been shown to affect cell–cell communication, membrane transport and process of energy generation, and peroxisome proliferation. In fish, PFOS can cause inflammation-independent leakage of liver cells and disturbance of DNA metabolism homeostasis in liver tissue, as well as an increase in hepatic fatty acyl-coenzyme A (CoA) oxidase activity, and oxidative damage. PFOS may also be an endocrine disruptor, and has been shown to alter steroid hormone and vitellogenin concentrations in plasma, and may be responsible for reduced fecundity and effects on ovaries.

Glossary

Ecological death Death attributed to natural processes such as predation; a result that contaminant exposure may increase the probability of.

Electro-olfactogram (EOG) The summed electrical response recorded from a group of receptor cells in response to an odorant stimulus.

Generator potential Local membrane depolarization in neurons, including OSNs, that may lead to an action potential.

Local effect Describes an effect that is limited to the site of application.

Pesticide A catchall term for agents/compounds that are intended to remove undesirable organisms; subcategories include herbicides, insecticides, and fungicides.

Pharmaceuticals A catchall term for agents/compounds that are intended to be of human medical use, such as fluoxetine.

Systemic effect Describes an effect that occurs spatially removed from the application site.

Introduction

At the headwaters of world renowned salmon runs in British Columbia, Canada, local fishermen offer testimonials of capturing returning adult fish that were completely blind. Without question we know that Pacific salmon rely on their sense of smell, that is, olfaction, to navigate much of their return river migration. However, salmon are not alone in their olfactory dependence; since discovering this remarkable ecophysiological phenomenon nearly 50 years ago, olfaction in fishes is now known to be necessary for migration of other fish species, for detecting predators, for recognizing related and unrelated fishes, for locating food, and for synchronizing the release of egg and sperm (**see also Smell, Taste, and Chemical Sensing**: Chemosensory Behavior). All of these indispensible behaviors are predicated on the functionality of the relatively unprotected olfactory sensory neurons (OSNs) of the nose. What a growing body of research demonstrates is that these neurons are not only exquisitely sensitive to dissolved odorants, but that they are also highly susceptible to impairment by exposure to the ever-increasing number of aquatic contaminants introduced into the aquatic ecosystem by humans. With unknown numbers of ecologically, culturally, and commercially invaluable fish stocks currently at risk for extinction, the need to understand the impact that contaminants make on olfactory-mediated behaviors has never been greater.

Understanding the ways that contaminants alter olfaction is challenging. The olfactory system is very complex and inextricably integrated into other suborganismal systems (**see also Smell, Taste, and Chemical Sensing**: Chemoreception (Smell and Taste): An Introduction). For this reason, isolating olfactory effects from others or determining the proportion of olfactory effects contributing to effects observed at the organismal level may not always be possible. Confounding all of this is that the mechanisms by which the majority of contaminants alter or interact with OSNs remains unknown. Nevertheless, an increasing number of techniques exist to investigate the effects and their mechanisms at organizational levels from the molecular to the behavioral. A growing field of research endeavor is the mechanistic linking of impaired enzyme expression/activity with behaviors that are relevant to survival. This article provides a succinct review of the relevant mechanics of olfaction, followed by a discussion on the known routes and examples by which contaminants affect olfaction and downstream responses, and finally directions are provided for future research.

Odorants, Contaminants, and Their Relevance to Physiological and Behavioral Response

Fishes live in a mosaic of dissolved compounds. The process of olfaction of a dissolved compound, that is, an odorant, begins with its binding to protein receptors at the apical surface of OSNs. The number of odorants is near limitless; the way in which they are perceived is not. Olfaction of chemical signals occurs through just 100–150 different distinct receptors, one type per OSN. There are three morphologically distinct OSN classes: ciliated, microvillar, and crypt. Each has specific types of receptor proteins. Ciliated OSNs express odorant receptor and vomero-nasal receptors, which bind amino acids and bile salts, respectively. Microvillus OSNs express vomero-nasal receptors and bind amino acids and nucleotides. Crypt OSNs express vomero-nasal receptors and may bind pheromones and/or amino acids. All OSNs transduce odorants using G-protein-coupled receptors (GPCRs), although the second messenger systems differ. In ciliated OSNs, G-proteins stimulate adenylate cyclase (AC) to produce cAMP, whereas in microvillar and crypt OSNs G-proteins stimulate phospholipase C to produce IP_3. In all OSNs, the second messengers act to open cation channels in the cell membrane, which then cause the membrane potential to depolarize. If the depolarization is sufficient (a generator potential), an action potential will be generated in an olfactory nerve and will be conducted back to the olfactory bulb (OB) for the first level of signal integration.

Second-order neurons in the OB may then conduct the signal to the higher brain (telencephalon, TE) for further processing and output, which may consist of physiological responses, such as hormone release or swimming behavior. (For more detailed information on fish olfaction, **see also Smell, Taste, and Chemical Sensing**: Morphology of the Olfactory (Smell) System in Fishes and Neurophysiology of Olfaction.)

The dissolved mosaic of compounds now includes many of human origin. As with all other life, fishes are adapted to the historic environment and its natural odorants and toxins. Humans have rapidly introduced pesticides, pharmaceuticals, and high concentrations of metals, to name just a few of the many types of contaminants. Our contributions are numerous and global, with contaminants reaching even the most remote and formerly pristine waterways. Just south of Alaska, for example, six classes of pesticides were found in a watershed virtually free of development; their presence can only be attributed to either aerial deposition or import courtesy of migratory fishes. In streams proximal to human activities, complex contaminant mixtures can consist of more than 50 compounds. This means that there is probably not a fish on the planet that will not be exposed to a synthetic contaminant that its olfactory machinery has been designed for, nor as of yet has had time to adapt to. Ideally, fishes that sense that they are in polluted water should move to other areas, and this has been shown in some cases for metals. However, migration may not be an option for some fishes (such as those that live in lakes), and there is no reason to expect that all contaminants will be perceived as noxious. In fact, some contaminants elicit behavioral attraction responses. Alarmingly, some fishes show an attraction response to toxicants. In other words, given the choice, fish may elect to put themselves in situations that will have negative fitness consequences.

The effects of the vast majority of aquatic contaminants on fish olfaction are unknown. Even when known for a specific compound, the effects of exposure to mixtures of compounds, as that they typically exist in, remain unknown. Furthermore, within a class of structurally similar compounds (e.g., carbamate insecticides), toxicities can differ considerably (e.g., >100-fold). Nevertheless, there are essentially four ways by which introduced agents can affect olfaction and its derived responses: (1) acting as odorants; (2) affecting the perception/reception of odorants; (3) indirectly altering neural circuitry associated with the processing of olfactory signals; and (4) impairing the functionality of processes necessary to an olfaction-based response, such as swimming ability (**Figure 1**). An ultimate goal of studies on olfaction and contaminants is to determine the relevance of the olfactory impairment to the survival of fishes in the environment.

Contaminants as Odorants

Generator potential responses of OSNs to natural odorants such as amino acids can be recorded with the help of small, sensitive electrodes placed immediately above the surface of the olfactory epithelium of a living fish (see **Figure 2**). The generator potentials, recorded as electro-olfactograms (EOGs), resemble action potentials, but are in fact the summed electrical responses of several neurons.

Contaminants can also generate EOGs, which means they would ultimately be perceived by the fish as odors. However, contaminants can generate EOGs through two routes: one analogous to odorants – by binding to odorant sites on GPCRs – and another not – by activating proteins associated with signal transduction (e.g., AC). In the former route, many contaminants have molecular components structurally similar to natural odorants, and so may bind existing GPCR-binding sites. One of the most widely used herbicides, Roundup®, contains an active ingredient (glyphosate) that evokes EOGs similar in magnitude to those of the amino acid L-serine (on a mass to mass basis). An OSN response to this active ingredient would not be unexpected since glyphosate is based on the amino acid glycine. As mentioned above, amino acids can activate both ciliated and microvillar OSNs. In contrast, contaminants may have no clear resemblance to amino acids, such as bile salts and pheromones, but can generate EOGs all the same, such as the insecticide carbaryl. Whether any given contaminant acts through GPCR binding, generator potential responses

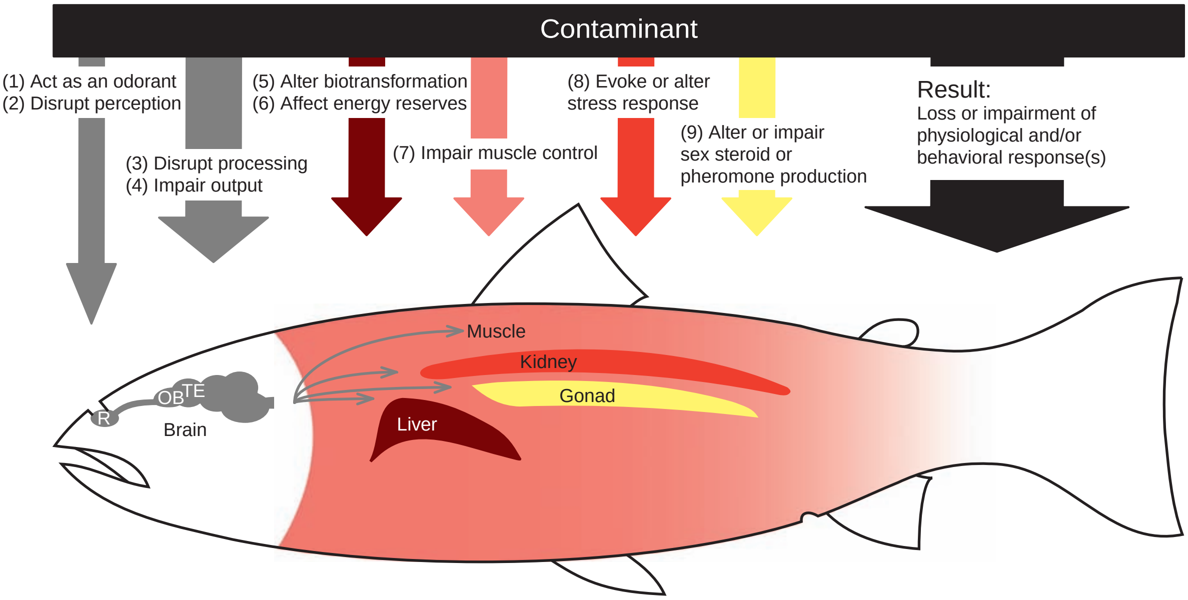

Figure 1 There are numerous routes by which contaminants can affect olfaction and downstream responses in fishes. The effects span from acting and competing with natural odorants, to altering the production of sex pheromones, to impairing behaviors critically important to survival, such as predator avoidance. OB, olfactory bulb; R, olfactory rosette; TE, telencephalon.

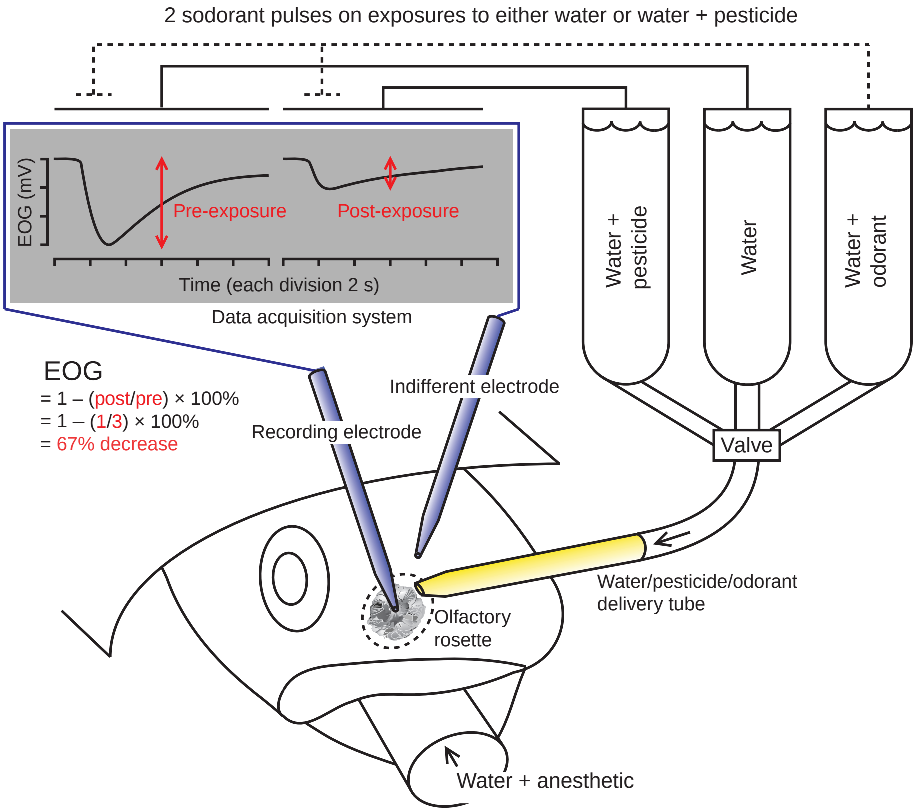

Figure 2 One of the best ways to determine whether contaminants affect olfactory neurons is to expose the olfactory tissue of anesthetized fish to contaminants and then pulse a known odorant of survival relevance over the tissue and measure responses. Decreased responses indicate olfactory impairment.

may be conducted back to the brain, and evoke physiological and/or behavioral responses. An issue is that contaminants that act through binding the odorant (i.e., ligand) site of a GPCR may also have added effects. Many contaminants have reactive, functional groups that may bind sites on the GPCRs or associated transduction machinery, and thereby inhibit/alter their functionality.

Contaminants That Impair OSNs

Being as exposed as they are, OSNs are open to a direct physical assault from waterborne compounds. Many contaminants affect OSNs structurally, even at the molecular level. These effects can occur very rapidly (<30 s) and persist (>20 min). Typically, impairments of this nature alter OSN responses to natural odorants such as amino acids (which have food, predator, and home stream olfactory bouquet (HSOB) relevance) and bile salts (which have social relevance). Therefore, impacts can be investigated by exposing either the isolated olfactory tissue (*in situ* preparations) or the whole animal (in tanks), and then recording the responses of OSNs to natural odorants (**Figure 2**). Exposure to altered pH, metals, pesticides, and other contaminants may all reduce OSN responses to amino acids.

Potent OSN toxicants include copper and certain pesticides, with impairment thresholds in the range of parts per billion (ppb) and lower. Copper was one of the very first contaminants investigated in this regard, and investigation continues owing to its release through mining activities and brake dust. Just a 30 min exposure to 5 ppm copper can reduce EOG response to L-serine (a predator scent) by as much as 50%. Synthetic compounds can have lower toxicity thresholds; OP and fungicide concentrations of ≤ 1 ppb can decrease L-serine EOGs to the same degree. Certain OSN toxic contaminants such as OPs have reactive functional groups, in this case phosphate groups (PO_4), that are known to bind with and inhibit enzymes, such as acetylcholinesterase (AChE). Although AChE may not be directly involved with olfaction, its functionality may be important to OSN function.

As may be expected, not all OSN types are equally sensitive to contaminants. The herbicide linuron, for example, reduces the L-serine EOGs, but not those for a bile salt (taurocholic acid, TChA). Differential impact on OSNs means that some behaviors may be selectively affected by contaminants. In this example, fish passing through a linuron-contaminated environment might not be as adept at avoiding predators, but would have no problem identifying kin. Overall, these types of effects are alarming since concentrations of these contaminants have been found repeatedly in fish bearing waterways.

OSNs can defend against contaminant insults. Chemical detoxification systems in OSNs and in the supporting tissues involve phase I and II detoxification enzymes that act to break up and/or solubilize compounds reaching and/or penetrating the olfactory epithelium. The expression of phase I and II enzymes can be induced by contaminant exposure; however, there is no guarantee that expression will be sufficient to stave off injury. At least one recent publication found that activity increases in a class of enzymes that solubilize compounds in order to facilitate their removal (glutathione S-transferase, GST) were insufficient to prevent OSN functionality impairments from realistic contaminant concentrations.

Contaminants That Affect Abilities Necessary to Olfaction-Based Responses

There are numerous routes by which contaminants can alter olfactory-based responses in addition to impairing OSNs. Many contaminants are readily miscible in water and are taken up by fishes (by gills, gut, and other routes). With uptake, contaminants may cause systemic effects through distribution beyond a local effect on OSNs.

Neurotoxic contaminants are prime candidates for causing systemic effects. The uptake of neurotoxins may impact the ability of the brain to process olfactory cues, affecting its ability to integrate olfactory responses with other external and internal signals of survival relevance as well as impairing the fish's ability to control muscle (**Figure 1**). Esfenvalerate (a pyrethroid) and chlorpyrifos (an OP) are two example neurotoxic contaminants that cause systemic effects. The pyrethroids impair the closing of the voltage-gated sodium channels that are critical for the generation of neuronal action potentials. As mentioned above, the OPs inhibit AChE, slowing the degradation of the neurotransmitter acetylcholine (ACh), which is involved in neuronal synapses in the brain as well as the neuromuscular synapses of skeletal, smooth, and cardiac muscles.

With the impairment of responses known to involve olfaction, a critical question is whether the downstream, systemic effect is more or less sensitive than the OSN local effect. Consider either impaired OSN responses or a change in desire/ability could contribute to a decrease in food odor response. Chlorpyrifos, for example, decreases OSN responses to TChA and L-serine following exposure to ≥ 1 ppb and impairs white muscle performance at concentrations ≥ 10 ppb. These data clearly suggest that the OSN impairment and not other effects would be of more behavioral relevance. The opposite is true for the herbicide atrazine, a common groundwater contaminant. Typically, exposure to female urine will evoke a priming response in male salmon and other species triggering an increase in plasma testosterone. Atrazine exposures in the parts per trillion (ppt) range can impair this response in male salmon, whereas OSN responses are not altered until the ppb range. Clearly varying sensitivities of orders of magnitude make predicting olfactory-based exposure outcomes very challenging.

One of the most intriguing olfactory paradoxes exists for migratory salmonids. As juveniles, they imprint to HSOB, which is used later to assist adult river navigation. Many of the streams that juveniles live in are filled with contaminants, including the two identified above as being odorants. As they mature, they will move out to the potentially or relatively cleaner ocean water. However, at maturity, they will return to freshwater and seek out that imprinted HSOB. Unfortunately, some of the contaminants they may have imprinted to over months of residence years earlier may now impair their OSNs because with relatively rapid transition to the freshwater environment, they will not have the detoxification machinery ready for coping with the contaminants. Without correct olfactory information, their ability to make accurate behavioral decisions (i.e., choose the right home stream) may be impaired.

Olfactory–Toxicity Interactions

The responses that olfactory cues evoke depend on the state of the animal. Broadly speaking, the signal is defined by the receiver. Therefore, contaminants that change the state of the animal can change the nature of an olfactory response. Well-known examples are contaminants that disrupt the endocrine system. Consider a male fish exposed to feminizing contaminants such as 4-nonylphenol (4-NP) for extended periods may respond as female to male pheromones. Although this type of effect is not directly an olfactory effect, it is through olfaction that the effect may be behaviorally evident.

Even in the short run, contaminants can act through the endocrine system to affect odorant responses. In fishes and other vertebrates, stress hormones can be upregulated following exposures to toxic compounds such as pesticides. Sensory cues perceived under a stressful situation may have altered meaning, or lose meaning altogether. For example, when fish are exposed to alarm pheromone (extract from conspecific skin), they typically exhibit an alarm response consisting of freezing. With pesticide exposure, these behaviors can be lost or worse: alarm pheromones can make fish more active. Such aberrant behavior may not result in outright death, but it may increase the probability of ecological death, such as through predation. Given many contaminants have multiple mechanisms of toxicity, interactions between sensory impairment and other physiological effects are likely common.

Even compounds that do not have overt toxicity, such as some polycyclic aromatic hydrocarbons, may have ramifications all the same. As discussed earlier, for a fish to remove (biotransform) compounds from the olfactory epithelium, proteins such as GSTs need to be made and so energy and nutrients are required. Coping with contaminant insult may take energy away from various olfactory-related processes, such as pheromone production and gonadal maturation.

Future Studies

Olfaction is an external to internal signal relay system that spans organizational levels, each interfaced by thresholds. Contaminants can act on the exposed OSNs, on the brain, on physiological systems in diverse ways, and through multiple pathways, all with potential to abolish or cause aberrant behaviors. The state-of-the-art research in olfactory toxicity research is two pronged, and consists of in-depth investigations at relatively low and high biological organizational levels. In the former, to elucidate the mechanisms of toxicity, molecular tools such as gene set analysis are being used. With knowledge of which genes undergo expression changes following contaminant exposure, we will be able to target candidate protein receptors and cellular systems. In the latter, behavioral endpoints using high-throughput screening methods are now available, in part, due to the wholesale adoption of zebrafish models. With behavioral endpoints of survival relevance, we will be able to predict how subtle changes in organism performance may alter their survivorship in the environment. With an increasing number of contaminants, with unpredictable changes in environmental condition (such as temperature), and with invasive species, the challenge is to determine how olfaction will function to ensure the success of fishes in a modern ecology.

Glossary

Aquaculture The rearing of aquatic organisms under controlled or semi-controlled conditions; sometimes referred to as underwater agriculture.

Bioenergetics Quantitative analysis of the energetic processes of living organisms.

Smoltification Series of physiological and morphological changes that a fish may undergo when migrating from freshwater to seawater.

Specific dynamic action (**SDA**) The additional amount of oxygen or energy consumed above standard metabolic rate (SMR) as a result of feeding, measured during the period after feeding until metabolic rate returns to SMR; SDA represents the energetic cost of digestion, assimilation, and protein turnover.

Introduction

Aquaculture, the rearing of aquatic organisms under controlled or semi-controlled conditions, is practiced for a variety of reasons. These include production of (1) food fish, (2) fish for stock enhancement (e.g., stocking Pacific salmon, *Oncorhynchus* spp., in the Pacific Northwest region of North America), and (3) aquarium fish, as well as captive rearing of rare or endangered fishes, either for reintroduction programs or to establish refuge populations. Regardless of the final disposition of the fish reared in aquaculture, the success of the culture operation largely depends on the culturist's ability to understand and manage the physiological responses of the cultured fish to their environment.

Maximizing fish production (kilogram of fish produced per unit time or kilogram of fish produced per unit volume of water), while simultaneously maintaining acceptable fish health and quality, can be achieved by providing optimal physiological conditions for growth and performance. Although this sounds superficially simple, the conflicting demands of maximizing profit wherein more fish need to be raised in a fixed amount of time and fixed amount of water versus the ability of the culturist to provide physiologically optimal conditions in a culture system with a high loading density make profitable aquaculture a challenging endeavor. Achieving a profitable equilibrium between culture conditions and production becomes especially difficult when fish are being raised under intensive conditions where the loading or stocking density of fish (kilogram of fish per unit volume water or unit flow of water) is high enough to exceed the natural carrying capacity of the culture vessel. In the most extreme cases, fishes that are reared in recirculating aquaculture systems can be held at very high densities ($>100\,000\ \mathrm{kg\,ha^{-1}}$).

Just about any aspect of fish physiology could have an effect on the success of an aquaculture operation; however, there are six key areas that generally apply in most situations and for most fishes: bioenergetics, the effects of temperature, oxygen and oxygen consumption rates, carbon dioxide and acid–base balance, osmoregulation and salinity tolerance, and swimming performance. Although seemingly distinct aspects of the physiology of fish, these components can be incorporated into the generalized bioenergetic framework proposed by Warren and Davis in 1967.

Bioenergetics

Food (energy) consumed by a fish is used to meet the metabolic demands of existing tissues, is lost to the environment as wastes, or, if it is in surplus, can be synthesized into new tissue. This accounting process is commonly referred to as the fish's energy budget, or bioenergetics. The general equation used to illustrate the partitioning of energy of fish in aquaculture (or other settings), as proposed by Warren and Davis in 1967, is given as

$$C = (M_r + M_a + \mathrm{SDA}) + (F + U) + (G_s + G_r)$$

where C is the energy consumption rate, M_r the standard metabolic rate, M_a the active metabolic rate, SDA the specific dynamic action, F the rate of energy loss in fecal matter, U the rate of energy loss in urine, G_s the rate of energy allocation to the growth of somatic tissues (proteins, lipids, and structural elements), and G_r the rate of energy allocation to the growth and maturation of reproductive tissues (**see also Temperature**: Measures of Thermal Tolerance).

In aquaculture, the general goal is to maximize the rate of G_s (sometimes also G_r), while minimizing the allocation of energy to the other compartments. Achieving this balance requires the culturist to maximize the surplus of energy available, while simultaneously providing physiologically optimum conditions for growth and minimizing the necessity for the fish to allocate energy to nongrowth compartments such as M_r or M_A. Reducing fish activity to levels that maximize the production of somatic tissue, and thus reducing M_a, is fairly straightforward and can be achieved through the careful design of the culture systems (e.g., raceways or tanks). Reducing the energy spent on various aspects of M_r, such as osmoregulation, oxygen uptake, and acid–base balance, requires greater effort because the physicochemical environment influences these aspects of a fish's physiology. Fortunately, our understanding and ability to manipulate environmental factors such as dissolved oxygen concentration, salinity, and pH are sufficiently advanced such that techniques and equipment are available to do so.

For further discussion on this topic within the encyclopedia, **see also Energetic Models**: Bioenergetics in Aquaculture Settings.

Temperature

Water temperature is the environmental variable that exerts the greatest influence on an aquaculture system. It not only directly affects the physiology of fish contained in the culture system, but also affects other physical and chemical variables, such as water viscosity, dissolved oxygen and carbon dioxide concentrations, and ammonia toxicity levels. The responses of various aspects of a fish's physiology to a change in temperature generally follow one of three patterns (**Figure 1**).

The first pattern (**Figure 1(a)**) shows a physiological function that is temperature independent. This is generally not observed in fish, except for a few eurythermal species or over ranges for which the Q10 (**see also Temperature**: Effects of Temperature: An Introduction) is small.

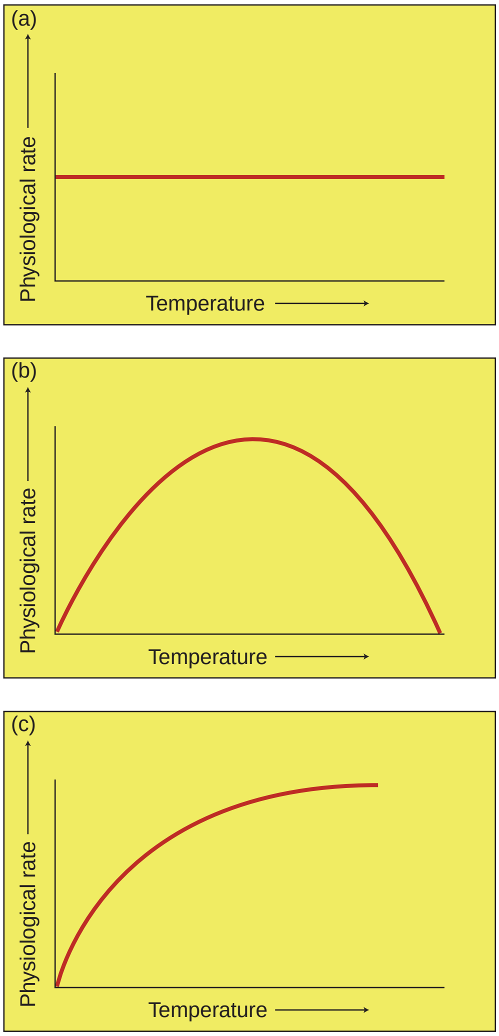

Figure 1 General responses of fish physiological processes to temperature showing possible temperature-independent (a) and temperature-dependent (b, c) patterns.

The second pattern (**Figure 1**(**b**)) is that observed for many physiological functions (e.g., growth rate) that increase with temperature to some maximum, often referred to as the optimal temperature for that function, and then decline as the temperature continues to increase.

The third pattern (**Figure 1**(**c**)) is where the rate of the physiological function (e.g., oxygen consumption rate) increases as temperature increases.

At the most fundamental level, a fish culturist should be cognizant of the temperatures that are tolerated by the species of interest at the acute and chronic levels, as well as the suboptimal and optimal temperatures for that species. **Figure 2** provides an example of such information for the rainbow trout (*Oncorhynchus mykiss*).

At the extremes of thermal tolerance are the acute upper and lower thermal limits, often referred to as the critical thermal maxima (CT_{max}) and critical thermal minima (CT_{min}). These are temperatures that the fish can survive for a short period of time (seconds to minutes) and still recover. For rainbow trout, the CT_{min} approaches 0 °C, while the CT_{max} ranges between 27 and 30 °C or more, depending on the acclimation temperature. Temperatures that are slightly more moderate than the critical thermal limits are often referred to as the incipient lethal limits, with the incipient upper lethal limit (IULT) and the incipient lower lethal limit (ILLT). These are temperatures that fish can tolerate for prolonged periods (hours to days) but that will ultimately prove lethal. For rainbow trout, the ILLT is close to 0 °C, while the IULT ranges from 25 to 27 °C, depending on the strain of trout and its acclimation temperature. Culturists do not typically rear fish under conditions approaching either incipient lethal or critical limits, except during unusual weather events or system failures. However, fish from aquaculture facilities that are released into the environment could encounter temperatures of this nature, adding value to this information.

Within the range bracketed by incipient lethal temperatures is a thermal region that contains both the optimal and the suboptimal, but not the lethal, temperatures. At suboptimal temperatures, a fish may not be able to fulfill its life cycle, but the individual fish can survive. For example, rainbow trout can survive and grow very well at 19 °C, but they spawn most successfully at temperatures below 10–12 °C. The optimal temperature range is the one where the rate of the physiological function is maximized. For rainbow trout, depending on the strain, the optimal range for growth lies between 15 and 19 °C.

Fish culturists try to rear fish at temperatures that approach the optimum for growth. It may be possible to provide fish with water of a constant temperature when spring-fed water supplies or recirculating culture systems are being used. If the primary water supply is subject to seasonal temperature fluctuations (e.g., from a local river or lake), then the culturist must understand the influences of temperature on metabolic processes and adjust their management accordingly (for further discussion on this topic, **see also Temperature**: Membranes and Temperature: Homeoviscous Adaptation).

When evaluating thermal tolerance data, one must consider the temperature to which the fish were acclimated (e.g., held for >2 weeks) prior to testing. Fishes have the ability to become thermally acclimated, thus slightly raising or lowering their ability to tolerate temperature extremes. There are limits to this acclimation, however, and it is generally considered impractical to try to acclimate coldwater species such as rainbow trout to temperatures more suitable for a warm-water species such as a Nile tilapia (*Tilapia niloticus*; optimal temperature 28–30 °C).

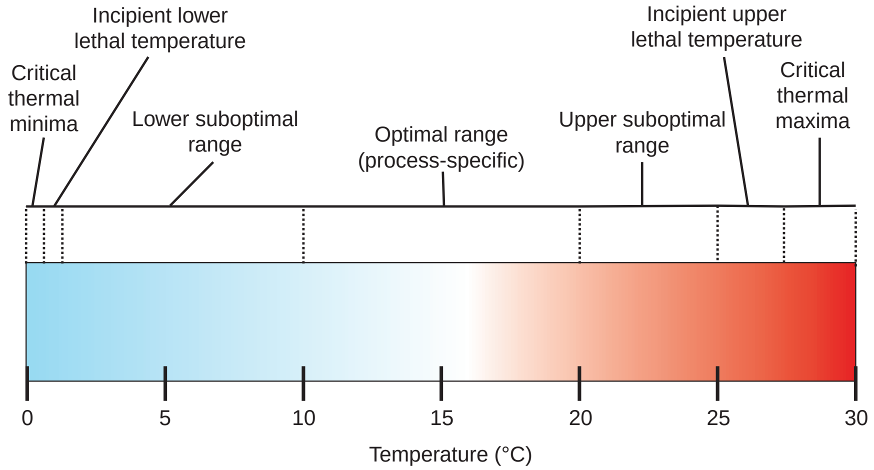

Figure 2 Thermal profile for rainbow trout (*Oncorhynchus mykiss*) showing critical thermal maxima and minima, incipient lethal temperatures, and suboptimal and optimal temperature ranges.

Oxygen and Oxygen Demand

After temperature, oxygen is the most influential of environmental factors when considering the physiology of fishes in aquaculture. The challenge in aquaculture, particularly in systems with a high fish-loading rate, is delivering sufficient oxygen to meet the metabolic demands of the fish to such a degree that no depression of growth is observed.

Effects of Mild Environmental Hypoxia

Under normal culture conditions, severe environmental hypoxia (low partial pressure of oxygen, P_{O_2}, in the water) is rare, and anoxia (zero oxygen) generally is not encountered. Severe environmental hypoxia is defined as P_{O_2} levels approaching the threshold P_{O_2} where there is insufficient oxygen for the organism to sustain a completely aerobic existence (**see also Hypoxia**: The Expanding Hypoxic Environment). The exceptions to this are during failures of aeration equipment, or when high densities of fish are confined in a small volume of water, such as in a fish-transport tank. When hypoxic conditions do occur, even at relatively mild levels (e.g., dissolved oxygen at 60% of air-saturated levels), long-term effects on fish growth and performance can be observed. The growth rate of fish, including rainbow trout and white sturgeon (*Acipenser transmontanus*), declines as the P_{O_2} decreases from normoxic (i.e., dissolved oxygen near air saturation) to hypoxic levels above the threshold P_{O_2}.

To avoid problems associated with mild levels of hypoxia, fish culturists use a variety of techniques to introduce atmospheric air, or for greater transfer efficiency, compressed and liquid oxygen into their culture systems to counter the fish's high oxygen demand. These aeration systems allow the rearing of fish at high stocking densities, and can also lead to complications related to carbon dioxide excretion and acid–base balance.

Sources of Increased Oxygen Demand in Cultured Fishes

How oxygen demand (or oxygen consumption rates) is affected by factors such as fish size, water temperature, activity, and SDA is discussed elsewhere in the encyclopedia (**see also Energetics**: General Energy Metabolism, **Temperature**: Effects of Temperature: An Introduction, and **Food Acquisition and Digestion**: Cost of Digestion and Assimilation). With regard to fish size, large fish use more oxygen than small fish, but small fish use more oxygen than large fish on a gram oxygen per gram fish basis (a higher mass-specific metabolic rate; **see also Energetics**: General Energy Metabolism). This is one of the reasons why aquaculture facilities that raise salmonids (members of family Salmonidae, including salmon, trout, and char) in raceways keep their smallest fish in the top raceways (receiving first-use water), while larger fish are held in the lower raceways (receiving second-, third-, or even fourth-use water). The raceways positioned further downstream contain less oxygen due to the respiration of the fish in the more upstream raceways.

Because fish oxygen demand also increases with water temperature, fish culturists need to monitor dissolved oxygen concentrations in their culture systems as daily and seasonal temperature fluctuations change the metabolic rates of the fish contained therein. The degree to which temperature affects metabolic rate and oxygen demand can be determined using the Q10 approach (for more details on this topic within the encyclopedia, **see also Temperature**: Effects of Temperature: An Introduction).

The specific dynamic action associated with the processing and assimilation of ingested food during daily culture operations can easily double oxygen demand for many hours. Recent studies on common carp (*Cyprinus carpio*), southern catfish (*Silurus meridionalis*), and other species demonstrated that the post-feeding oxygen demands can be 2–4 times as high as the pre-feeding oxygen demand. This increased oxygen demand generally peaks within 2–6 h after feeding and remains elevated for periods exceeding 24 h, depending on the water temperature. Clearly, this is something that a fish culturist needs to account for, along with increases in microbial oxygen consumption rates within the system that may accompany SDA increases as the flux of nitrogenous wastes stimulates higher levels of bacterial activity. The timing, magnitude, and duration of the SDA effect are affected by feed composition (in particular, the source and proportion of protein to other ingredients). In addition, fish size, meal size, and feeding frequency can all affect the timing, magnitude, and duration of the SDA effect (for more details on this topic within the encyclopedia, (**see also Food Acquisition and Digestion**: Cost of Digestion and **Integrated Response of the Circulatory System**: Integrated Responses of the Circulatory System to Digestion).

Carbon Dioxide and Acid–Base Balance

When fish in a culture system use oxygen to meet their aerobic metabolic demands, they produce carbon dioxide (CO_2) that is transported from the tissues by the blood to the gills, where it is excreted. Because of the nature of the carbonate system, the addition of aqueous carbon dioxide to the environment (culture system) will decrease the pH, leading to problems with environmental acidosis; these conditions can have negative impacts on fish growth and on the performance of culture system components such as biofiltration units.

If the carbon dioxide is allowed to build up in the culture system, the water becomes hypercarbic (synonymous with hypercapnic, which is a term often used in the literature). Studies on white sturgeon showed that severe hypercapnia (45–75 $\mathrm{mg\,L^{-1}}$ CO_2) reduces growth by 38% compared with fish held under normocarbic (synonymous with normocapnic) conditions. Similar effects have been seen in juvenile Atlantic salmon (*Salmo salar*) and juvenile spotted wolffish (*Anarhichas minor*). The juvenile wolffish also showed signs of nephrocalcinosis, but this may have resulted from a combination of factors, including high environmental carbon dioxide levels and dietary sources such as magnesium deficiencies or an unbalanced feed mineral composition.

Hypercarbic conditions during fish-transport operations can impact the post-transport survival of fish. Walleye (*Sander vitreus*) transported in tanks where the P_{CO_2} was allowed to increase had higher blood P_{CO_2}, bicarbonate ion concentrations ($[HCO_3^-]$), and stress indicators (plasma cortisol and blood glucose) than fish transported in tanks fitted with ram-air scoops that prevented the increase in water P_{CO_2}. Such measures, along with vigorous aeration of water in static culture systems, particularly those using oxygen injection systems, can prevent problems with hypercarbic conditions that would otherwise lead to a disruption of the ability of the fish to maintain an adequate internal acid–base balance (for more details on fish acid–base balance and hypercapnia effects, **see also Transport and Exchange of Respiratory Gases in the Blood**: Carbon Dioxide Transport and Excretion).

Osmoregulation, Salinity Tolerance, and Smoltification in Cultured Fishes

A detailed discussion of osmoregulation, salinity tolerance, and smoltification in cultured fishes is beyond the scope of this article. However, some portions of these topics are relevant to aquaculture, primarily those regarding the stress response and stress mitigation, and in relation to the parr–smolt transformation of juvenile anadromous salmonids.

Osmoregulation – Implications for Aquaculture

When fish encounter stressful conditions, their responses include primary, secondary, and tertiary stages. One phase of the secondary response is an increase in gill perfusion through lamellar recruitment and an increase in gill permeability. While such actions are adaptive in that they allow for greater oxygen uptake, they also allow for greater water and solute fluxes, and thus can disrupt ionic and osmoregulatory stability if the stressor persists – termed the 'osmo-respiratory compromise'. Fish in aquaculture become stressed during many standard culture activities including cleaning of culture vessels, handling, transportation, and crowding. Evidence from careful monitoring of stress indicators, including plasma cortisol concentrations and plasma glucose levels, suggests that the most stressful periods are those involving handling and air exposure. Mortality resulting from an osmoregulatory disturbance may be delayed by 24 h or more. Fish chronically exposed to sublethal levels of stress will show reduced growth rates and have higher rates of disease incidence (**see also Role of the Gills**: The Osmorespiratory Compromise).

In addition to adopting culture practices that minimize the rough handling of fishes, careful management of water quality, and, in particular, water temperature and salinity, can help reduce the osmotic gradients between the fish and their environment, thus reducing the osmotic and ionic gradients that are present. A general approach is to add sodium chloride (NaCl) at concentrations of 1–5 $\mathrm{g\,L^{-1}}$ to the system water and to reduce the water temperature by up to 5 °C from the source tank. Studies on largemouth bass (*Micropterus salmoides*) hauled in water that had NaCl added and that was cooled demonstrated that posthaul survival could be doubled, particularly when the posthaul fish were held in water that also had salt added to it. In addition to simple NaCl solutions, there are a number of commercially available solutions designed to mitigate the effects of stress on fish. Some of the solutions are designed to reduce the toxicity of ammonia; a similar effect can be achieved by using granular zeolite (synonymous with clinoptilolite). While these commercial formulations have been shown to be effective, most have not been approved for use on food fish; therefore, fish culturists should consult the manufacturers and regional regulatory agencies before employing them (**see also Nitrogenous-Waste Balance**: Excretion of Ammonia).

Salinity Tolerance

Managing the salinity tolerance of fish in aquaculture is primarily a concern of culturists raising anadromous salmonids such as Atlantic salmon and Arctic char (*Salvelinus alpinus*) that combine a freshwater rearing phase of fry and juveniles with a longer saltwater grow-out period. The attraction of the saltwater grow-out period includes the greater availability of space and water, a potential reduction in the number of diseases, and the potential for higher growth rates in saltwater, as many wild strains of salmonids grow faster in seawater than in freshwater.

Recognizing the transformation of the freshwater-adapted juveniles into seawater-adapted juveniles and timing the subsequent transfer of the fish into saltwater culture systems is critical – moving juvenile fish that are not capable of osmoregulating in seawater will generally cause high levels of mortality. The timing of such movements is well established for Atlantic and Pacific salmon, but is still being determined for emerging species such as Arctic char. In the case of some strains of Arctic char, growth was highest in salinities of 0–10 ppt, and fish transferred to salinities of 20–30 ppt had higher mortality rates and lower growth rates.

For more information on the physiological aspects of osmoregulation and salinity tolerance within the encyclopedia, **see Osmotic, Ionic and Nitrogenous-Waste Balance**: Osmoregulation in Fishes: An Introduction.

Exercise and Cultured Fishes

Cultured fishes are generally held in tanks, raceways, or net pens that provide a heterogeneous velocity field. While this velocity heterogeneity may provide fish with areas where they can rest and reduce energy expenditures (reducing M_a), it does not always provide the greatest benefit in terms of growth potential. Studies on the effects of mild exercise (forced swimming at 1–2 body lengths per second) on striped bass (*Morone saxatilis*) and rainbow trout have demonstrated that fish that are forced to exercise can demonstrate higher growth rates than those that only engage in volitional swimming. The trade-off is that the higher growth rates are associated with higher food consumption rates; hence, fish culturists should conduct a cost–benefit analysis to determine if the gain in production is offset by the increased production costs. There may be other benefits of the exercise, such as flesh quality.

Another area where subjecting cultured fish to exercise may be beneficial is when the fish are being raised for stock enhancement. Studies have shown that exercised fish have swimming performances that are closer to those of wild fish than cultured fish that do not experience an exercise regime. This increased swimming performance can help prevent the higher rates of downstream displacement, predation mortality, and release stress that cultured fish often experience.

INDEX

NOTES:

Cross-reference terms in *italics* are general cross-references, or refer to subentry terms within the main entry (the main entry is not repeated to save space). Readers are also advised to refer to the end of each article for additional cross-references – not all of these cross-references have been included in the index cross-references.

The index is arranged in set-out style with a maximum of three levels of heading. Major discussion of a subject is indicated by **bold** page numbers. Page numbers suffixed by *t* and *f* refer to Tables and Figures respectively. *vs.* indicates a comparison.

This index is in letter-by-letter order, whereby hyphens and spaces within index headings are ignored in the alphabetization. Prefixes and terms in parentheses are excluded from the initial alphabetization.

ABBREVIATIONS:

Ca^{2+} – calcium
CO_2 – carbon dioxide
DNA – deoxyribonucleic acid
ELL – electrosensory lateral line lobe
EOD – electric organ discharge
GABA – γ-aminobutyric acid
GM – genetically modified
H_2S – hydrogen sulfide
HPI axis – hypothalamic – pituitary – interrenal axis
IGF – insulin-like growth factor
MCHC – mean cell hemoglobin concentration
MRC – mitochondrion-rich cell
NaCl – sodium chloride
NKA – Na^+/K^+-ATPase
NKCC – Na^+, K^+, $2Cl^-$ cotransporter
OSN – olfactory sensory neuron
PAHs – polycyclic aromatic hydrocarbons
PBDEs – polybrominated diphenyl ethers
PCBs – polychlorinated biphenyls
RBC – red blood cell
SDA – specific dynamic action
TNF – tumor necrosis factor

  definition, 2, 6
  evolution/developmental transformation, 7*f*, 8
    craniates, 11–13, 12*f*
    tunicates, 11
Neural depression, anoxic crucian carp, 1828
Neural electrocytes, 389, 389*f*
Neural mechanisms, sex change *see under* Sex change
Neural network, definition, 387
Neural plasticity *see* Plasticity
Neural regulation, color changes, 493
Neural responses, magnetic fields *see under* Magnetic sense
Neural tube, 2–3, 3*f*
  definition, 2
Neuraxis, definition, 2
Neuroanatomy, magnetic sense, 732, 733*f*
Neurodegenerative, definition, 1986
Neurodegenerative diseases, fish models in, 1993
Neuroendocrine axis
  definition, 1542
  see also Hypothalamic–pituitary–interrenal (HPI) axis
Neuroepithelial bodies (NEBs), 872, 875, 877
  definition, 871
Neuroepithelial cells (NECs), gill, 872, 1097*f*, 1100, 1754*f*, 1755
  definition, 871
  innervation, 873, 874*f*
  location/distribution, 872, 873*f*
  oxygen sensing role *see* Oxygen chemoreceptors, branchial
Neuroethology
  definition, 329
  electrocommunication as model, 706
  lateral line function studies, 329–330
    see also Lateral line function
  psychoacoustics and, **276–282**
Neurogenesis, suppression in ectoderm, 9
Neurogenic electric organs, 414*f*, 414–415
  definition, 409
Neurogenic placodes, 8, 14
  definition, 6, 283
  see also Placodes
Neurohormones
  appetite regulating, 1510, 1512, 1512*t*
  definition, 1509, 1515
  see also specific neurohormones
Neurohypophysis, 1458
  definition, 1457
  histology, 1458, 1458*f*, 1459*f*, 1460*f*
    adenohypophysis relations, 1458, 1460*f*
    elasmobranchs, 1458–1459, 1460*f*
    lamprey, 1459, 1461*f*
  hormones, 1462
  see also Pituitary gland
Neuro–immuno–endocrine network, stress response, 1547*f*, 1548
  time course activation, 1548*f*, 1549
Neurokinin A (NKA)
  amino acid sequence, 1337, 1338*f*
  gut expression, 1338
  see also Tachykinins
Neuromast(s)
  canal *see* Canal neuromasts
  cupula *see* Cupula
  definition, 236, 329, 336, 1937
  eels, 1942
  papillate, 334–335
    definition, 329
  sensory hair cells, 330*f*, 336, 337*f*, 338*f*
    innervation, 337–338
    orientation, 330–331, 337, 337*f*, 340*f*, 342*f*
  structure and function, 336, 337*f*, 338*f*
  superficial *see* Superficial neuromasts
  see also Lateral line
Neuromeres
  cartilaginous fish, 27–29, 32
  definition, 16, 26
  forebrain *see* Prosomeres
  hindbrain *see* Rhombomere(s)
Neuromeric model, definition, 16
Neuronal nitric oxide synthase (nNOS), 1069
  intracardiac, ray-finned fish, 1069, 1070*f*
Neurons
  action potential generation, 1717*f*, 1720
  evolution, 7, 8
  intracardiac *see* Intracardiac neurons/neurotransmitters
  sensory nerve endings, 189, 192
  see also Motor neurons; *specific neurons*
Neuropeptide(s), 1069
  definition, 649, 656, 1067, 1542
  enteric nervous system, 1332, 1336
  see also specific neuropeptides
Neuropeptide Y (NPY), 1279–1280, 1281, 1337
  amino acid sequence, 1337*f*
  appetite stimulation, 1484, 1512, 1512*t*
  gut expression, 1337
  role in rectal gland secretion control, 1435
Neurophysiology
  gustation *see* Gustation, neurophysiology
  olfaction *see* Olfaction, neurophysiology
Neuroscience, fish models in, 1993
  neurodegenerative diseases, 1993
Neurosecretion, definition, 1457
Neurosecretory cells
  definition, 1483
  hypothalamo-hypophysial system, 1458, 1459*f*, 1459*f*
    see also Neurohypophysis
Neurotoxins
  anthropogenic, 786
  olfactory effects, 2081
Neurotransmitters, 786, 1069, 1190–1191
  anthropogenic disruptions, 786

- Neurotransmitters (*continued*)
  - definition, 649, 783, 1190
  - effect of social status on levels, 652
  - enteric nervous system *see under* Enteric nervous system
  - intracardiac *see* Intracardiac neurons/neurotransmitters
